mpatrol

A library for controlling and tracing dynamic memory allocations
Edition 1.7 for mpatrol version 1.1.3
23rd March, 2000

mpatrol

This document describes mpatrol, a library for controlling and tracing dynamic memory allocations.

This is edition 1.7 of the mpatrol manual for version 1.1.3, 23rd March, 2000.

Foreword

I first started writing this library a few years ago when the company I work for sent me out to a customer who had reported a memory leak, which he expected was coming from the code generated by our C++ compiler. A few years on and the library has changed dramatically from its first beginnings, but I thought I'd release it publicly in case anyone else found it useful.

When writing the library, I placed more emphasis on the quantity and quality of information about allocated memory rather than the speed and efficiency of allocating the actual memory. This means that the library will use dramatically more memory than normal dynamic memory allocation libraries and can slow down to a crawl depending on which options you use. However, the end results are likely to be accurate and reliable, and in most cases the library will run quite happily at a sane speed.

The mpatrol library is by no means the only library of its kind. Solaris 7 has no less that 6 different malloc libraries, and there are plenty available as freeware or as commercial products. Try to keep in mind that mpatrol comes with absolutely no warranty and so if it doesn't work for you and you need a fast solution, try some of the other libraries or products available. I have listed some of the most popular at the end of this manual (see Appendix G [Related software], page 101).

This manual is arranged so that complete reference material on the mpatrol library can be found in the appendices, while introductory and background material can be found in the preceding chapters and sections. For readers who wish to delve right in and use the library, the Installation (see Chapter 3 [Installation], page 11) and Examples (see Chapter 10 [Examples], page 43) chapters should be enough to get started. Otherwise, this manual should be read from beginning to end in order to get the most out of the software it describes.

Due to their very nature, problems with dynamic memory allocations are notoriously difficult to reproduce and debug, and this is likely to be the case if you find a bug in the mpatrol library as it might be extremely hard to reproduce on another system. Details on how to report bugs are given elsewhere in this document (see Appendix F [Notes], page 95), but it would be very useful if you could try to provide as much information as possible when reporting a problem, and that includes having a look in the library source code to see if it's obvious what is wrong. However, please try to read the FAQ first in case your question or problem is covered there since it is usually updated every time I receive a question about mpatrol.

The latest version of the mpatrol library and this manual can always be found at `http://www.cbmamiga.demon.co.uk/mpatrol/`, and any correspondence relating to mpatrol (bug reports, enhancement requests, compliments, etc.) should be sent to `mpatrol@cbmamiga.demon.co.uk`. The mpatrol library is also registered at FreshMeat (`http://freshmeat.net/`) so you can receive notification of updates there as well. I normally only check my e-mail about once or twice a week, so don't expect an immediate response. I can also be reached at `graeme@epc.co.uk` but that is my work e-mail address. There is now also a discussion group at `http://www.egroups.com/group/mpatrol/` where you can post mpatrol-related questions but you must first subscribe to the group before you can send mail to it.

Note that this manual is not just intended to instruct readers on how to use the mpatrol library — it is also written to give a detailed look at how malloc libraries work in general and how to improve the efficiency of existing code which uses them. If this subject interests you, you may find further useful material at *The Memory Management Reference* located at http://www.harlequin.com/mm/reference/. It has links to many documents and research papers in the field of memory management, and has a large glossary which lists and explains related terms. You may also wish to look at *A Memory Allocator* by Doug Lea for information on general memory allocation principles. It is located at http://gee.cs.oswego.edu/dl/html/malloc.html.

Finally, I'd like to thank Stephan Springl (springl@bfw-online.de) for his help on reading debugging information from object files via the GNU BFD library, and Dave Gibson (david@epc.co.uk) for his help on writing thread-safe code. Calum Wilkie (calum@epc.co.uk) also deserves a mention since the idea for providing stack traces comes from a similar library he wrote a few years ago.

Oh, and always remember to do final release builds without the mpatrol library as the library is much slower than normal malloc implementations and uses much more memory.

Happy debugging!

Graeme Roy, 11th October, 1999.

Edinburgh, Scotland.

1 Overview

The mpatrol library is yet another link library that attempts to diagnose run-time errors that are caused by the wrong use of dynamically allocated memory. If you don't know what the `malloc()` function or `operator new[]` do then this library is probably not for you. You have to have a certain amount of programming expertise and a knowledge of how to run a command line compiler and linker before you should attempt to use this.

Along with providing a comprehensive and configurable log of all dynamic memory operations that occurred during the lifetime of a program, the mpatrol library performs extensive checking to detect any misuse of dynamically allocated memory. All of this functionality can be integrated into existing code through the inclusion of a single header file at compile-time. On UNIX and Windows platforms (and AmigaOS when using `gcc`) this may not even be necessary as the mpatrol library can be linked with existing object files at link-time or, on some platforms, even dynamically linked with existing programs at run-time.

All logging and tracing output from the mpatrol library is sent to a separate log file in order to keep its diagnostics separate from any that the program being tested might generate. A wide variety of library settings can also be changed at run-time via an environment variable, thus removing the need to recompile or relink in order to change the library's behaviour.

The mpatrol library has been designed with the intention of replacing calls to existing C and C++ memory allocation functions as seamlessly as possible, but in many cases that may not be possible and slight code modifications may be required. However, a preprocessor macro containing the version of the mpatrol library is provided for the purposes of conditional compilation so that release builds and debug builds can be easily automated.

2 Features

An overall list of features contained in the mpatrol library is given below. This is not intended to be exhaustive since the best way to see what the library does is to read the documentation and try it out.

- Written for UNIX, AmigaOS, Windows and Netware platforms.
- Can be built to allocate memory from a fixed-sized static array rather than using heap memory from the system.
- Can be built as archive, shared and/or thread-safe libraries on systems that support them, or even as one large object file.
- Details of memory allocations and free memory are stored internally as a tree structure for speed and also to allow the best fit allocation algorithm to be used. This also enables the library to perform intelligent resizing of memory allocations and can be used to quickly determine if an address has been allocated on the heap.
- Contains 14 replacement C dynamic memory allocation functions:

`malloc()`	ANSI	Allocates memory.
`calloc()`	ANSI	Allocates zero-filled memory.
`memalign()`	UNIX	Allocates memory with a specified alignment.
`valloc()`	UNIX	Allocates page-aligned memory.
`pvalloc()`	UNIX	Allocates a number of pages.
`strdup()`	UNIX	Duplicates a string.
`strndup()`	old	Duplicates a string with a maximum length.
`strsave()`	old	Duplicates a string.
`strnsave()`	old	Duplicates a string with a maximum length.
`realloc()`	ANSI	Resizes memory.
`recalloc()`	old	Resizes memory allocated by `calloc()`.
`expand()`	old	Resizes memory but does not relocate it.
`free()`	ANSI	Frees memory.
`cfree()`	old	Frees memory allocated by `calloc()`.

- Contains 4 replacement C++ dynamic memory allocation functions:

`operator new`	Allocates memory.
`operator new[]`	Allocates memory for an array.
`operator delete`	Frees memory.
`operator delete[]`	Frees memory allocated by `operator new[]`.

- Contains 9 replacement C memory operation functions:

`memset()`	ANSI	Fills memory with a specific byte.
`bzero()`	UNIX	Fills memory with the zero byte.
`memcpy()`	ANSI	Copies non-overlapping memory.
`memmove()`	ANSI	Copies possibly-overlapping memory.
`bcopy()`	UNIX	Copies possibly-overlapping memory.
`memcmp()`	ANSI	Compares two blocks of memory.
`bcmp()`	UNIX	Compares two blocks of memory.
`memchr()`	ANSI	Searches memory for a specific byte.
`memmem()`	UNIX	Searches memory for specific bytes.

- Contains support for a user-defined low-memory handler function, including a replacement for the C++ function, `set_new_handler()`.
- Contains support for user-defined prologue and epilogue callback functions, which get called before and after every memory allocation, reallocation or deallocation.
- A function is provided to return as much information as possible about a given memory allocation, and can be called at any time during program execution.
- A function is provided to display library settings and heap usage statistics, including peak memory usage. This information is also displayed at program termination.
- The library reads any user-controllable options at run-time from an environment variable, but this does not have to be set as defaults will then be used. This prevents having to recompile anything in order to change any library settings. An option exists to display a quick-reference summary of all of the recognised options to the standard error file stream.
- All diagnostics and logging are sent to a file in the current directory, but this can be overridden, including forcing the log file to be the standard output or standard error file streams.
- Options exist to log details of every memory allocation, reallocation or deallocation when they occur.
- Options exist to halt the program at a specific memory allocation, reallocation or deallocation when running the program within a debugger. These options have no effect when running the program without a debugger.
- On UNIX platforms, the `mmap()` function can optionally be used to allocate memory instead of the `sbrk()` function, but only if the system supports it. This can be useful if the mpatrol library clashes with another malloc library that uses `sbrk()` to allocate heap memory.
- On non-UNIX platforms where the mpatrol library overrides `malloc()` without requiring the inclusion of '`mpatrol.h`', versions of the UNIX functions `brk()` and `sbrk()` are provided for compatibility with certain libraries. These should *not* be called by user code as they have only limited functionality.
- All newly-allocated memory that is not allocated by the `calloc()` or `recalloc()` functions will be pre-filled with a non-zero value in order to catch out programs that wrongly assume that all newly-allocated memory is zeroed. This value can be modified at run-time.
- Can automatically check to see if there have been any illegal writes to bytes located just before and after every memory allocation through the use of overflow buffers. The size of such overflow buffers and the value to pre-fill them with can be modified at run-time. The checks will be performed before every memory allocation call to ensure that nothing has overwritten the overflow buffers, but a function is also provided to perform additional checks under the programmer's control and an option exists to specify a range in which checks will be performed.
- On systems that support them, watch point areas can be used instead of overflow buffers so that every read and write to memory is checked to ensure that it is not within an overflow buffer.
- Can automatically check to see if there have been any illegal writes to free memory blocks. The value to pre-fill free memory blocks with can be modified at run-time. The

check will be performed before every memory allocation call to ensure that nothing has overwritten the free memory block, but a function is also provided to perform additional checks under the programmer's control and an option exists to specify a range in which checks will be performed.

- On systems that support memory protection, every memory allocation can optionally be allocated at least one page of memory. That way, any free memory blocks can be made read and write protected so that nothing can access free memory on the heap. An option is provided to specify whether all memory allocations should be allocated at the start or at the end of such pages, and the bytes left over within the pages become overflow buffers.
- All freed memory allocations can optionally be prevented from being returned to the free memory pool. This is useful for detecting if use is being made of freed memory just after a memory allocation has been freed. The contents of the memory allocation can either be preserved or can be pre-filled with a value in order to detect illegal writes to the freed memory allocation.
- Calls to memory operation functions (such as `memset()` or `memcpy()`) have their arguments checked to ensure that they do not pass null pointers or attempt to read or write memory straddling the boundary of a previously allocated memory block. Tracing from all such functions can also optionally be written to the log file.
- The internal data structures used by the library are kept separate from the rest of the memory allocations. On systems that support memory protection, all of these internal data structures will be write-protected in order to prevent corruption by the calling program. This feature can be overridden at run-time as it can slow the program down.
- Certain signals can be saved and restored on entry to each library function and `errno` is set to `ENOMEM` if memory cannot be allocated.
- On systems that support memory protection, the library attempts to detect any illegal memory accesses and display as much information as it can obtain about the address in question and where the illegal memory access occurred.
- A call stack traceback from any function performing a memory allocation is stored if the library supports this feature on the system it is being run on. This information can then be displayed when information about a specific memory allocation is required. Two different call stack traceback implementations are provided.
- Symbol table details from executable files and shared libraries are automatically read on systems that support this feature in order to make the call stack tracebacks more meaningful. An option also exists to display a complete list of the symbols that were read by the library at program termination.
- Compiler-generated line number tables from any debugging sections that exist in executable files and shared libraries can also be used by the mpatrol library in order to provide more meaningful information in call stack tracebacks.
- If the library is unable to automatically determine a program's executable filename to read symbols from then an option exists to specify the full path to the program's executable file.
- An option exists to change the default alignment used for general-purpose memory allocations.

- Contains support for a user-defined limit to available memory which can be useful for stress-testing a program in simulated low memory conditions.
- Contains a feature to randomly fail a specific frequency of memory allocations which can be useful for stress-testing error recovery code in a program.
- An option exists to display a complete memory map of the heap at program termination. A function to do this is also available to call at any point during program execution.
- Options exist to display all freed and unfreed memory allocations at program termination in order to detect memory leaks.
- An option exists to abort the program with a failure condition if there are more than a specified number of unfreed memory allocations at program termination. This could be useful for batch testing in order to check that all tests free up most of their allocated memory.
- Functions always report if their arguments are illegal in order to pinpoint any errors, and options exist to perform rigorous checking of arguments when allocating, reallocating and freeing memory. In addition, checking is performed to ensure that memory allocated by `operator new[]` is not freed with `free()` for example.
- The type of function performing a memory allocation is always stored along with the allocation, as well as the file and line number it was called from. If compiled with `gcc`, the function name will also be stored and the thread identifier will be stored if using the thread-safe library.
- The library uses a header file to redefine the memory allocation functions as macros in order to obtain more information about where they were called from. This is not strictly required on UNIX and Windows platforms (and AmigaOS when using `gcc`), since the library automatically redefines the default system memory allocation functions.
- A shell script is supplied for UNIX platforms to run a program that was linked with the mpatrol library with any specified options on the command line. On some UNIX platforms, an option also exists to override the default memory allocation routines for any dynamically-linked program that was not previously linked with the mpatrol library.
- A small test suite is provided in order to test basic features.
- User documentation is currently available in TEXinfo format as well as UNIX manual pages.

3 Installation

The mpatrol library was initially developed on an Amiga 4000/040 running AmigaOS 3.1. I then installed Redhat Linux 5.1 on my Amiga and added support for Linux/m68k. I've tried my best to make it as easy as possible to build and install mpatrol on any system, but it isn't likely to run smoothly for everybody. However, there shouldn't be any major problems if you perform the following steps.

1. Go into the '`build`' directory and then into the appropriate subdirectory for your system.
2. Edit the '`Makefile`' in that directory and check that it is using the appropriate compiler and build tools. The `CC` macro specifies the compiler, the `AR` macro specifies the tool used to build the archive library and the `LD` macro specifies the tool to build the shared library. The `CFLAGS` macro specifies compiler options that are always to be used, the `OFLAGS` macro specifies optimisation options for the compiler, the `SFLAGS` macro specifies options to be passed to the compiler when building a shared library and the `TFLAGS` macro specifies options to be passed to the compiler when building a thread-safe library. You may also need to change the library names and library build commands on different systems.
3. Use the `make` command (or equivalent) to build the mpatrol library in archive form. The '`all`' target builds all possible combinations of the mpatrol library for your system. The '`clean`' target removes all relevant object files from the current directory, while the '`clobber`' target also removes all libraries that have been built from the current directory.
4. Copy all of the libraries that have been built into your local library directory. If there were symbolic links created in the '`build`' directory then these should be recreated in the local library directory rather than simply copying them.
5. Go up two directory levels into the '`src`' directory and copy the '`mpatrol.h`' header file into your local include directory.
6. On UNIX platforms, go up one directory level into the '`bin`' directory and copy the '`mpatrol`' shell script into your local bin directory.
7. On UNIX platforms, go up one directory level into the '`man`' directory and copy the '`man1`' and '`man3`' subdirectories to your local man directory. Unfortunately, the location for manual pages varies from system to system so you may or may not also be able to copy the '`cat1`' and '`cat3`' subdirectories as well. The '`man*`' subdirectories contain the unformatted manual pages while the '`cat*`' subdirectories contain the formatted manual pages.
8. Go up one directory level into the '`doc`' directory and examine the files located there. The '`mpatrol.texi`' file contains the TEXinfo source for this manual and can be translated into a wide variety of documentation formats. There may already be translated files in the '`doc`' directory, but if not you will either have to generate them yourself using an appropriate tool or you could download an archive containing the latest mpatrol manual in a variety of documentation formats from the mpatrol home page. You can then install or print these documents.

Alternatively, the '`pkg`' directory contains files that can be used to automatically generate a *package* in a specific format suitable for installation on a system. Two package formats

(PKG and RPM) and two archive formats are currently supported (generic tape archive and LhA). The first package format is generally used on UNIX SVR4 systems, while the second was introduced by Red Hat for use in their Linux distributions. The generic tape archive can be used as a distribution for UNIX systems where no package format is supported, but it does not contain information on how to install the files on the system once they have been extracted from the distribution. The LhA format is roughly the same, but is intended for Amiga systems and is used for Aminet distributions. You should really know what you are doing before you attempt to build a package, and you should also be aware that some of the package files may need to be modified before you begin.

4 Integration

The following steps should allow you to easily integrate the mpatrol library into an existing application, although some of them may not be available to do on many platforms. They are listed in the order of number of changes required to modify existing code — the last step will require a complete recompilation of all your code.

1. This step is currently only available on Solaris platforms.

   If your program or application has been dynamically linked with the system C library ('`libc.so`') or an alternative malloc shared library then you can use the '`-d`' option to the '`mpatrol`' shell script to override the default definitions of `malloc()`, etc. at run-time without having to relink your program.

   For example, if your program's executable file is called '`testprog`' and it accepts an option specifying an input file, you can force the system's dynamic linker to use mpatrol's versions of `malloc()`, etc. instead of the default versions by typing:

   ```
   mpatrol -d ./testprog -i file
   ```

   The resulting log file should be called '`mpatrol.<procid>.log`' by default (where *procid* is the current process id), but if no such file exists after running the '`mpatrol`' shell script then it will not be possible to force the run-time linking of mpatrol functions to your program and you will have to proceed to the next step.

2. This step is currently only available on UNIX and Windows platforms (and AmigaOS when using `gcc`).

   You should be able to link in the mpatrol library when linking your program without having to recompile any of your object files or libraries, but this will only be worthwhile on systems where stack tracebacks are supported, otherwise you should proceed to the next step since there will not be enough information for you to tell where the calls to dynamic memory allocation functions took place.

   Information on how to link the mpatrol library to an application is given at the start of the examples (see Chapter 10 [Examples], page 43), but you should note that if your program does not directly call any of the functions in the mpatrol library then it will not be linked in and you will not see a log file being generated when you run it. You can force the linking of the mpatrol library by causing `malloc()` to be undefined on the link line, usually through the use of the '`-u`' linker option.

3. All of the following steps will require you to recompile some or all of your code so that your code calls dynamic memory allocation functions from the mpatrol library rather than the system C library.

   For this step, if you have a rough idea of where the function calls lie that you would like to trace or test, you need only recompile the relevant source files. You should modify these source files to include the '`mpatrol.h`' header file before any calls to dynamic memory allocation or memory operation functions.

   However, you should take particular care to ensure that all calls to memory allocation functions in the mpatrol library will be matched by calls to memory reallocation or deallocation functions in the mpatrol library, since if they are unmatched then the log file will either fill up with errors complaining about trying to free unknown allocations, or warnings about unfreed memory allocations at the end of execution.

4. This step requires you to recompile all of your source files to include the '`mpatrol.h`' header file. Obviously, this will take the longest amount of time to integrate, but need not require you to change any source files if the compiler you are using has a command line option to include a specific header file before any source files.

   For example, `gcc` comes with a '`-include`' option which has this feature, so if you had to recompile a source file called '`test.c`' then the following command would allow you to include '`mpatrol.h`' without having to modify the source file:

   ```
   gcc -include /usr/local/include/mpatrol.h -c test.c
   ```

5 Memory allocations

In the C and C++ programming languages there are generally three different types of memory allocation that can be used to hold the contents of variables. Other programming languages such as Pascal, BASIC and FORTRAN also support some of these types of allocation, although their implementations may be slightly different.

5.1 Static memory allocations

The first type of memory allocation is known as a *static memory allocation*, which corresponds to file scope variables and local static variables. The addresses and sizes of these allocations are fixed at the time of compilation[1] and so they can be placed in a fixed-sized data area which then corresponds to a section within the final linked executable file. Such memory allocations are called static because they do not vary in location or size during the lifetime of the program.

There can be many types of data sections within an executable file; the three most common are normal data, BSS data and read-only data. BSS data contains variables and arrays which are to be initialised to zero at run-time and so is treated as a special case, since the actual contents of the section need not be stored in the executable file. Read-only data consists of constant variables and arrays whose contents are guaranteed not to change when a program is being run. For example, on a typical SVR4 UNIX system the following variable definitions would result in them being placed in the following sections:

```
int a;           /* BSS data */
int b = 1;       /* normal data */
const int c = 2; /* read-only data */
```

In C the first example would be considered a *tentative* declaration, and if there was no subsequent definition of that variable in the current translation unit then it would become a *common* variable in the resulting object file. When the object file gets linked with other object files, any common variables with the same name become one variable, or take their definition from a non-tentative definition of that variable. In the former case, the variable is placed in the BSS section. Note that C++ has no support for tentative declarations.

As all static memory allocations have sizes and address offsets that are known at compile-time and are explicitly initialised, there is very little that can go wrong with them. Data can be read or written past the end of such variables, but that is a common problem with all memory allocations and is generally easy to locate in that case. On systems that separate read-only data from normal data, writing to a read-only variable can be quickly diagnosed at run-time.

5.2 Stack memory allocations

The second type of memory allocation is known as a *stack memory allocation*, which corresponds to non-static local variables and call-by-value parameter variables. The sizes of these allocations are fixed at the time of compilation but their addresses will vary depending on when the function which defines them is called. Their contents are not immediately

[1] Or more accurately, at link time.

initialised, and must be explicitly initialised by the programmer upon entry to the function or when they become visible in scope.

Such memory allocations are placed in a system memory area called the *stack*, which is allocated per process[2] and generally grows down in memory. When a function is called, the state of the calling function must be preserved so that when the called function returns, the calling function can resume execution. That state is stored on the stack, including all local variables and parameters. The compiler generates code to increase the size of the stack upon entry to a function, and decrease the size of the stack upon exit from a function, as well as saving and restoring the values of registers.

There are a few common problems using stack memory allocations, and most generally involve uninitialised variables, which a good compiler can usually diagnose at compile-time. Some compilers also have options to initialise all local variables with a bit pattern so that uninitialised stack variables will cause program faults at run-time. As with static memory allocations, there can be problems with reading or writing past the end of stack variables, but as their sizes are fixed these can usually easily be located.

5.3 Dynamic memory allocations

The last type of memory allocation is known as a *dynamic memory allocation*, which corresponds to memory allocated via `malloc()` or `operator new[]`. The sizes, addresses and contents of such memory vary at run-time and so can cause a lot of problems when trying to diagnose a fault in a program. These memory allocations are called dynamic memory allocations because their location and size can vary throughout the lifetime of a program.

Such memory allocations are placed in a system memory area called the *heap*, which is allocated per process on some systems, but on others may be allocated directly from the system in scattered blocks. Unlike memory allocated on the stack, memory allocated on the heap is not freed when a function or scope is exited and so must be explicitly freed by the programmer. The pattern of allocations and deallocations is not guaranteed to be (and is not really expected to be) linear and so the functions that allocate memory from the heap must be able to efficiently reuse freed memory and resize existing allocated memory on request. In some programming languages there is support for a *garbage collector*, which attempts to automatically free memory that has had all references to it removed, but this has traditionally not been very popular for programming languages such as C and C++, and has been more widely used in functional languages like ML[3].

Because dynamic memory allocations are performed at run-time rather than compile-time, they are outwith the domain of the compiler and must be implemented in a run-time package, usually as a set of functions within a linker library. Such a package manages the heap in such a way as to abstract its underlying structure from the programmer, providing a common interface to heap management on different systems. However, this *malloc library* must decide whether to implement a fast memory allocator, a space-conserving memory allocator, or a bit of both. It must also try to keep its own internal tables to a minimum so

[2] Or per thread on some systems.

[3] There is currently at least one garbage collection package available for C and C++ (see Appendix G [Related software], page 101).

as to conserve memory, but this means that it has very little capability to diagnose errors if any occur.

In some compiler implementations there is a builtin function called `alloca()`. This is a dynamic memory allocation function that allocates memory from the stack rather than the heap, and so the memory is automatically freed when the function that called it returns. This is a non-standard feature that is not guaranteed to be present in a compiler, and indeed may not be possible to implement on some systems. However, some compilers now support variable length arrays which provide roughly the same functionality.

As can be seen from the above paragraphs, dynamic memory allocations are the types of memory allocations that can cause the most problems in a program since almost nothing about them can be used by the compiler to give the programmer useful warnings about using uninitialised variables, using freed memory, running off the end of a dynamically-allocated array, etc. It is these types of memory allocation problems that the mpatrol library loves to get its teeth into!

6 Operating system support

Beneath every malloc library's public interface there is the underlying operating system's memory management interface. This provides features which can be as simple as giving processes the ability to allocate a new block of memory for themselves, or it can offer advanced features such as protecting areas of memory from being read or written. Some embedded systems have no operating systems and hence no support for dynamic memory allocation, and so the malloc library must instead allocate blocks of memory from a fixed-sized array. The mpatrol library can be built to support all of the above types of system, but the more features an operating system can provide it with, the more it can do.

On operating systems such as UNIX and Windows, all dynamic memory allocation requests from a process are dealt with by using a feature called *virtual memory*. This means that a process cannot perform illegal requests without them being denied, which protects the other running processes and the operating system from being affected by such errors. However, on AmigaOS and Netware platforms there is no virtual memory support and so all processes effectively share the same address space as the operating system and any other running processes. This means that one process can accidentally write into the data structures of another process, usually causing the other process to fail and bring down the system. In addition, a process which allocates a lot of memory will result in there being less available memory for other running processes, and in extreme cases the operating system itself.

6.1 Virtual memory

Virtual memory is an operating system feature that was originally used to provide large usable address spaces for every process on machines that had very little physical memory. It is used by an operating system to fool[1] a running process into believing that it can allocate a vast amount of memory for its own purposes, although whether it is allowed to or not depends on the operating system and the permissions of the individual user.

Virtual memory works by translating a virtual address (which the process uses) into a physical address (which the operating system uses). It is generally implemented via a piece of hardware called a *memory management unit*, or MMU. The MMU's primary job is to translate any virtual addresses that are referred to by machine instructions into physical addresses by looking up a table which is built by the operating system. This table contains mappings to and from *pages*[2] rather than bytes since it would otherwise be very inefficient to handle mappings between individual bytes. As a result, every virtual memory operation operates on pages, which are indivisible and are always aligned to the system page size.

Even though each process can now see a huge address space, what happens when it attempts to allocate more pages than actually physically exist, or allocate an additional page of memory when all of the physical pages are in use by it and other processes? This problem is solved by the operating system temporarily saving one or more of the least-used

[1] Well, perhaps that's too harsh a word, but it will certainly seem that way to a process running on a 32-bit UNIX system with only 4 megabytes of physical memory, and yet it will be able to read from and write to over 4 gigabytes of virtual memory!

[2] The size of a page varies between operating systems and processor architectures, but they are generally around 4 or 8 kilobytes in size, and are always a power of two.

pages (which might not necessarily belong that that process) to a special place in the file system called a *swap file*, and mapping the new pages to the physical addresses where the old pages once resided. The old pages which have been *swapped out* are no longer currently accessible, but their location in the swap file is noted in the translation table.

However, if one of the pages that has been swapped out is accessed again, a *page fault* occurs at the instruction which referred to the address and the operating system catches this and reloads the page from the swap file, possibly having to swap out another page to make space for the new one. If this occurs too often then the operating system can slow down, having to constantly swap in and swap out the same pages over and over again. Such a problem is called *thrashing* and can only really be overcome by using less virtual memory or buying more physical memory.

It is also possible to take advantage of the virtual memory system's interaction between physical memory and the file system in program code, since mapping an existing file to memory means that the usual file I/O operations can be replaced with memory read and write operations. The operating system will work out the optimum way to read and write any buffers and it means that only one copy of the file exists in both physical memory and the file system. Note that this is how *shared libraries*[3] on UNIX platforms are generally implemented, with each individual process that uses the shared library having it mapped to somewhere in its address space.

Another major feature of virtual memory is its ability to read protect and write protect individual pages of process memory. This means that the operating system can control access to different parts of the address space for each process, and also means that a process can read and/or write protect an area of memory when it wants to ensure that it won't ever read or write to it again. If an illegal memory access is detected then a *signal* will be sent to the process, which can either be caught and handled or will otherwise terminate the process. Note that as with all virtual memory operations, this ability to protect memory only applies to pages, so that it is not possible to protect individual bytes.

However, some versions of UNIX have programmable software *watch points* which are implemented at operating system level. These are normally used by debuggers to watch a specified area of memory that is expected to be read from or written to, but can just as easily be used to implement memory protection at byte level. Unfortunately, as this feature is implemented in software[4] rather than in hardware, watch points tend to be incredibly slow, mainly as a result of the operating system having to check every instruction before it is executed.

There is also an additional problem when using watch points, which is due to misaligned reads from memory. These can occur with compiler-generated code or with optimised library routines where memory read, move or write operations have been optimised to work at word level rather than byte level. For example, the `memcpy()` function would normally be written to copy memory a byte at a time, but on some systems this can be improved by copying a word at a time. Unfortunately, care has to be taken when reading and writing such words as the equivalent bytes may not be aligned on word boundaries. Technically, reading additional bytes before or after a memory allocation when they share the same word is legal, but when using watch points such errors will be picked up. The mpatrol library

[3] DLLs on Windows platforms.

[4] The operating system is still considered software.

replaces most of the memory operation functions provided by the system libraries with safer versions, although they may not be as efficient.

An operating system with virtual memory is usually going to run ever so slightly slower than an operating system without it[5], but the advantages of virtual memory far outweigh the disadvantages, especially when used for debugging purposes.

6.2 Call stacks and symbol tables

As stated in the section on stack memory allocations (see Section 5.2 [Stack memory allocations], page 15), when a function is called, a copy of the caller's state information (including local variables and registers) is saved on the stack so that it can be restored when the called function returns. On many operating systems there is a *calling convention*[6] which defines the layout of such stack entries so that code compiled in different languages and with different compilers can be intermixed. This usually specifies at which stack offsets the stack pointer, program counter and local variables for the calling function can be found, although on some processor architectures the function calling conventions are specified by the hardware and so the operating system must use these instead.

On systems that have consistent calling conventions, it is usually possible to perform call stack *tracebacks* from within the current function in order to determine the stack of function calls that led to the current function. This is extremely useful for debugging purposes and is done by examining the current stack frame to see if there is a pointer to the previous stack frame. If there is, then it can be followed to find out all of the state information about the calling function. This can be repeated until there are no more stack frames. This is generally how this information is determined by debuggers when a call stack traceback is requested.

In addition to the pointer to the previous stack frame, the saved state information also always contains the saved program counter register, which contains either the address of the instruction that performed the function call, or the address of the instruction at which to continue execution when the called function returns[7]. This information can be used to identify which function performed the call, since the address of the instruction must lie between the start and end of one of the functions in the process.

However, in order to determine this symbolic information, it must be possible to find out where the start and end addresses of all of the functions in the process are. This can usually only be read from object files, since they contain the symbol tables that were used by the linker to generate the final executable file for the program. The object file's symbol tables normally contain information about the start address, size, name and visibility of every symbol that was defined, but this depends on the format of the object file and if the symbol tables have been stripped from the final executable file.

If the object file was created by a compiler then it may also contain debugging information that was generated by the compiler for use with a debugger. Such information may

[5] Due to the overhead of having to translate every address and swap in and out pages — although memory mapped files will usually be more efficient than using normal file operations on a system without virtual memory.

[6] Usually part of the *Application Binary Interface*, or ABI.

[7] Also known as the *return address*.

include a mapping of code addresses to source lines[8], and this information can be used by the mpatrol library to provide more meaningful information in call stack tracebacks.

On systems that support shared libraries, additional work must be done to determine the symbolic information for all of the functions which have been defined in them. The symbols for functions that are defined in shared libraries normally appear as undefined symbols in the executable file for the program and so must be searched in the system in order to get the necessary information. It is usually necessary to liaise with the *dynamic linker*[9] on many systems.

6.3 Threads

On systems with virtual memory, such as UNIX and Windows, user programs are run as *processes* which have their own address space and resources. If a process needs to create sub-processes to perform other tasks it must call `fork()` or `spawn()` to create new processes, but these new processes do not share the same address space or resources as the parent process. If processes need to share memory they must either use a message passing interface or explicitly mark a range of memory as shareable.

Traditionally, this was not too much of a handicap as parallel processing was an expensive luxury and could only be made use of by the kernel of such systems. However, with the birth of fast processors and parallel programming, programs could be made to run more efficiently and faster on multi-processor systems by having more than one *thread* of control. This was achieved by allowing processes to have more than one program counter through which the processor could execute instructions, and if one thread of control stalled for a particular reason then another could continue without stalling the entire process.

Such multithreaded programs allow parallel programming and implicit shared memory between threads since all threads in a process share the same address space and resources. This is similar to operating systems that have no virtual memory, such as AmigaOS and Netware[10], except that once a process terminates, all threads terminate as well and all of its resources are still reclaimed.

Multithreaded programming generally needs no compiler support, but does require some primitive operations to be supported by the operating system for a threads library to call. The functions that are available in the threads library provide the means for a process to create and destroy threads. There are currently several popular threads libraries available, although the POSIX threads standard remains the definitive implementation.

It is always important to remember when programming a multithreaded application that because all threads in a process share the same address space, measures must be taken to prevent threads reading and writing global data in a haphazard fashion. This can either be done by locking with semaphores and mutexes, or can be performed by using stack variables instead of global variables since every thread has its own local stack. Care must be taken to write re-entrant functions — i.e. a function will give exactly the same result with one thread as it will with multiple threads running it at the same time.

---

[8] Generally known as a line number table.

[9] Which is the part of the operating system that performs the run-time linking of shared libraries.

[10] Where the kernel is effectively a single process running all user programs as threads.

7 Using mpatrol

This chapter contains a general description of all of the features of mpatrol and how to use them effectively. You'll also find a complete reference for mpatrol in the appendices, but you may wish to try out the examples (see Chapter 10 [Examples], page 43) and the tutorial (see Chapter 11 [Tutorial], page 63) before reading further.

7.1 Library behaviour

Most of the behaviour of the mpatrol library can be controlled at run-time via options which are read from the `MPATROL_OPTIONS` environment variable. This prevents you having to recompile or relink each time you want to change a library setting, and so makes it really easy to try out different settings to locate a particular bug. You should know how to set the value of an environment variable on your system before you read on.

By default, the mpatrol library will attempt to determine the minimum required alignment for any generic memory allocation when it first initialises itself. This may be affected by the compiler and its settings when the library was built but it should normally reflect the minimum alignment required by the processor on your system. If you would prefer a larger (or perhaps even smaller) default alignment you may change it at run-time using the '`DEFALIGN`' option. The value you supply must be in bytes, must be a power of two, and should not be larger that the system page size. If you encounter bus errors due to misaligned memory accesses then you should increase this value.

On systems that have virtual memory the library will attempt to write-protect all of its internal structures when user code is being run. This ensures that it is nearly impossible for a program to corrupt any mpatrol library data. However, unprotecting and then protecting the structures at every library call has a slight overhead so you may prefer to disable this behaviour by using the '`NOPROTECT`' option. This has no effect on systems that have no virtual memory.

Usually it is desirable for many system library routines to be protected from being interrupted by certain signals since they may themselves be called from signal handlers. If this is not the case then it may be possible to interrupt the program from within such routines, perhaps causing problems if their global variables are left in an undefined state. As the mpatrol library replaces some of these system library routines it is also possible to specify that they are protected from certain interrupt signals using the '`SAFESIGNALS`' option. However, this can sometimes result in it being hard to interrupt the program from the keyboard if a lot of processor time is spent in mpatrol routines, which is why this behaviour is disabled by default[1].

On UNIX systems, the usual way for malloc libraries to allocate memory from the process heap is through the `sbrk()` system call. This allocates memory from a contiguous heap, but has the disadvantage in that other library functions may also allocate memory using the same function, thus creating holes in the heap. This is not a problem for mpatrol, but you may have a suspicion that your bug is due to a function from another library corrupting your data so you may wish to use the '`USEMMAP`' option. This is only available on systems that have the `mmap()` system call and allows mpatrol to allocate all of its memory from a

[1] In mpatrol release 1.0 it was enabled by default.

part of the process heap that is non-contiguous (i.e. each call to `mmap()` may return a block of memory that is completely unrelated to that returned by the previous call).

By default, every time an mpatrol library function is called the library will automatically check the freed memory and overflow buffers of every memory allocation, which can slow program execution down, especially if you suspect the error you are looking for occurs at the 1000th memory allocation, for example. You can therefore use the '`CHECK`' option to specify a range of memory allocations at which the mpatrol library will automatically check the freed memory and overflow buffers. All other allocations that fall outside this range will not be checked.

If the mpatrol library that was built for your system supports reading symbolic information from a program's executable file, but it cannot locate the executable file, or you wish to specify an alternative, you can use the '`PROGFILE`' option to do this. All this does is instruct the mpatrol library to read symbols from this file instead. Note that on systems that support dynamic linking, the library can also read symbols from a dynamically linked executable file that has had its normal symbol table stripped.

Finally, a list of all of the recognised options in the mpatrol library can be displayed to the standard error file stream by using the '`HELP`' option. This will not affect the settings of the library in any way, so you should be able to use other options at the same time.

7.2 Logging and tracing

If you would like to see a complete log of all of the memory allocations, reallocations and deallocations performed by your program, use the '`LOGALL`' option. This provides detailed tracing for each of the mpatrol library functions, and a full description of the format of such tracing is given in Example 1 (see Section 10.1 [Example 1], page 43). Alternatively, you may select one or more types of functions to be traced using the '`LOGALLOCS`', '`LOGREALLOCS`', '`LOGFREES`' and '`LOGMEMORY`' options if you feel that the log file is too large when '`LOGALL`' is used. By default all diagnostics from the mpatrol library get sent to '`mpatrol.log`' in the current directory, but this can be changed using the '`LOGFILE`' option.

On systems that support it, every log entry also contains a call stack traceback that may also include the names of the symbols that appear on the call stack. If the object file access library that mpatrol was built with has support for reading line number tables from object files then the '`USEDEBUG`' option will also try to determine the file name and line number for each entry in the call stack, but only if the object files contain the relevant debugging information. This information will only be available before program termination and so any call stack tracebacks that appear after the library summary will not be displayed with their corresponding file name and line number. This option will also slow down program execution since a search through the line number tables will have to be made every time a call stack is displayed.

The mpatrol library will always try to display as much useful information as possible in this log file, and will always display a summary of library settings and statistics when your program terminates successfully. If you don't get this then your program did not call `exit()` and either called `abort()` or was terminated by the operating system instead. In such cases, either use a debugger to see where your program crashed or use the '`LOGALL`' option to see the last successful library call in the log file so that you have a rough idea of where your program crashed.

It is also possible to get mpatrol to write more summary information to the log file after it writes out its settings and statistics at program termination. Use the '`SHOWFREED`' and '`SHOWUNFREED`' options to display a list of freed and unfreed memory allocations. The former will only be displayed if the '`NOFREE`' option is used, but the latter can be useful for detecting memory leaks. The '`SHOWMAP`' option will display a memory map of the heap that was valid when the process terminated, and the '`SHOWSYMBOLS`' option will display any symbolic information that the mpatrol library managed to obtain from any executable files and libraries that were relevant to the program being tested. All of these options can be selected with the '`SHOWALL`' option.

7.3 General errors

By default, the mpatrol library follows the guidelines for ANSI C regarding the behaviour of the dynamic memory allocation functions it replaces[2]. This means that calling `malloc()` with a size of zero is allowed, for example. However, warnings can be generated for all of these types of calls by using the '`CHECKALL`' option. The '`CHECKALLOCS`' option warns only about calls to `malloc()` and similar functions with a size of zero, the '`CHECKREALLOCS`' option warns only about calls to `realloc()` and similar functions with either a null pointer or a size of zero, and the '`CHECKFREES`' option warns only about calls to `free()` and similar functions with a null pointer.

All newly-allocated memory can be pre-filled with a specified byte by using the '`ALLOCBYTE`' option. This can be used to catch out code that expects newly-allocated memory to be zeroed, although this option will have no effect on memory that was allocated with `calloc()`. All free memory can also be pre-filled with a different specified byte by using the '`FREEBYTE`' option. This will catch out code that expects to be able to use the contents of freed memory.

Alternatively, the mpatrol library can be instructed to keep all freed memory allocations so that its diagnostics can be clearer about which freed allocation a piece of code is erroneously trying to access. This is controlled with the '`NOFREE`' option, but since it never reuses any freed allocations it can result in a lot more heap memory being used. Note that this option distinguishes between *free* memory and *freed* memory. *Free* memory is unallocated memory that has been taken from the system heap. *Freed* memory is a freed memory allocation, with all of the original details of the allocation preserved.

Normally, the '`NOFREE`' option will fill the freed allocation with the free byte so that any code that accesses it will hopefully fall over. However, the original contents can be preserved using the '`PRESERVE`' option in case you need to see what the contents were just before it was freed. The '`NOFREE`' option is also affected by the '`PAGEALLOC`' option, since then the freed allocation will have its contents both read and write protected so that nothing can access them. If the '`PRESERVE`' option is used in this case then the freed allocation will only be made write-protected so that the original contents can be read from but not written to.

[2] I attempted to do the same for ANSI C++ but there are still namespace and exception handling issues to be resolved.

7.4 Overwrites and underwrites

Once a block of memory has been allocated, it is imperative that the program does not attempt to write any data past the end of the block or write any data just before the beginning of the block. Even writing a single byte just beyond the end of an allocation or just before the beginning of an allocation can cause havoc. This is because most malloc libraries store the details of the allocated block in the first few words before the beginning of the block, such as its size and a pointer to the next block. The mpatrol library does not do this, so a program which failed using the normal malloc library and worked when the mpatrol library was linked in is a possible candidate for turning on overflow buffers.

Such memory corruption can be extremely difficult to pinpoint as it is unlikely to show itself until the next call is made to the malloc library, or if the internal malloc library blocks were not overwritten, the next time the data is read from the block that was overwritten. If the former is the case then the next library call will cause an internal error or a crash, but only when the memory block that was affected is referenced. This is likely to disappear when using the mpatrol library since it keeps its internal structures separate, and write-protects them on systems that support memory protection.

In order to identify such errors, it is possible to place special buffers[3] on either side of every memory allocation, and these will be pre-filled with a specified byte. Before every mpatrol library call, the library will check the integrity of every such overflow buffer in order to check for a memory underwrite or overwrite. Depending on the number of allocations and size of these buffers, this can take a noticable amount of time (which is why overflow buffers are disabled by default), but can mean that these errors get noticed sooner. The option which governs this is '`OFLOWSIZE`'. The byte with which they get pre-filled can be changed with '`OFLOWBYTE`'. Depending on what gets written, it might only be possible to see such errors when a different size of buffer or a different pre-fill byte is used.

A worse situation can occur when it is only reads from memory that overflow or underflow; i.e. with the faulty code reading just before or just past a memory allocation. These cannot be detected by overflow buffers as it is not possible using conventional means to interrupt every single read from memory. However, on systems with virtual memory, it is possible to use the memory protection feature to provide an alternative to overflow buffers, although at the added expense of increased memory usage.

The '`PAGEALLOC`' option turns on this feature and automatically rounds up the size of every memory allocation to a multiple of the system page size. It also rounds up the size of every overflow buffer to a multiple of the system page size so that every memory allocation occupies its own set of pages of virtual memory and no two memory allocations occupy the same page of virtual memory. The overflow buffers are then read and write protected so that any memory accesses to them will generate an error[4]. Following on from the previous section, the '`PAGEALLOC`' option also causes free memory to be read and write protected as well since that will also occupy non-overlapping virtual memory pages.

The remaining memory that is left over within an allocation's pages is effectively turned into traditional overflow buffers, being pre-filled with the overflow byte and checked periodically by the mpatrol library to ensure that nothing has written into them. However,

[3] Commonly known as *overflow buffers* or *fence posts*.

[4] This is a feature that was first used by Electric Fence (see Appendix G [Related software], page 101) to track down memory corruption.

because of this remaining memory, the library has a choice of where to place the memory allocation within its pages. If it places the allocation at the very beginning then it will catch memory underwrites, but if it places the allocation at the very end then it will catch memory overwrites. Such a choice can be controlled at run-time by supplying an argument to the '`PAGEALLOC`' option. If '`PAGEALLOC=LOWER`' is used then every allocation will be placed at the very beginning of its pages and if '`PAGEALLOC=UPPER`' is used then the placement will be at the very end of its pages. This is probably better explained in Example 3 (see Section 10.3 [Example 3], page 53) where the problems with '`PAGEALLOC=UPPER`' and alignment are also discussed.

Obviously, there are still some deficiencies when using '`PAGEALLOC`' since it can use up a huge amount of memory (especially with '`NOFREE`') and the overflow buffers within an allocation's pages can still be read without causing an immediate error. Both of these deficiencies can be overcome by using the '`OFLOWWATCH`' option to install *software watch points* instead of overflow buffers, but there are still very few systems that support software watch points at the moment, and it can slow a program's execution speed down by a factor of around 10,000. The reason for this is that software watch points instruct the operating system to check every read from and write to memory, which means that it has to single-step through a process checking every instruction before it is executed. However, this is a very thorough way of checking for overflows and is unlikely to miss anything, although there may be problems with misaligned memory accesses when using watch points (see Section 6.1 [Virtual memory], page 19).

Note that from release 1.1.0 of mpatrol, the library comes with replacement functions for many memory operation functions, such as `memset()` and `memcpy()`. These new functions provide additional checks to ensure that if a memory operation is being performed on a memory block, the operation will not read or write before or beyond the boundaries of that block.

To conclude, if you suspect your program has a piece of code which is performing illegal memory underwrites or overwrites to a memory allocation you should use each of the following options in sequence, but only if your system supports them.

1. '`OFLOWSIZE=8`'
2. '`OFLOWSIZE=32`'
3. '`OFLOWSIZE=1`' '`PAGEALLOC=LOWER`'
4. '`OFLOWSIZE=1`' '`PAGEALLOC=UPPER`'
5. '`OFLOWSIZE=8`' '`OFLOWWATCH`'
6. '`OFLOWSIZE=32`' '`OFLOWWATCH`'

7.5 Using with a debugger

If you would like to use mpatrol to pause at a specific memory allocation, reallocation or deallocation in a debugger then this section will describe how to go about it. Unfortunately, debuggers vary widely in function and usage and are normally very system-dependent. The example below will use `gdb` as the debugger, but as long as you know how to set a breakpoint within a debugger, any one will do.

First of all, decide where you would like the mpatrol library to pause when running your program within the debugger. You can choose one allocation index to break at using the

'ALLOCSTOP' option, or you can choose to break at a specific reallocation of that allocation by also using the 'REALLOCSTOP' option. If you use 'REALLOCSTOP' without using 'ALLOCSTOP' then you will break at the first memory allocation that has been reallocated the specified number of times. You can also choose to break at the point in your program that frees a specific allocation index by using the 'FREESTOP' option.

The normal process for determining where you would like to pause your program in the debugger is by using the 'LOGALL' option and examining the log file produced by mpatrol. If your program crashed then you should look at the last entry in the log file to see what the allocation index (and possibly also the reallocation index) of the last successful call was. You can then decide which of the above options to use. Note that the debugger will break at a point before any work is done by the mpatrol library for that allocation index so that you can see if it was the last successful operation that caused the damage.

Having decided which combination of mpatrol options to use, you should set them in the MPATROL_OPTIONS environment variable before running the debugger on your program. Alternatively, your debugger may have a command that allows you to modify your environment during debugging, but you're just as well setting the environment variable before you run the debugger as it shouldn't make any difference[5].

After you get to the debugger command prompt, you should set a breakpoint at the __mp_trap() function. This is the function that gets called when the specified allocation index and/or reallocation index appears and so when you run your program under the debugger the mpatrol library will call __mp_trap() and the debugger will stop at that point. If you are not running your program within a debugger, or if you haven't set the breakpoint, then __mp_trap() will still be called, but it won't do anything. Note that there may be some naming issues on some platforms where the visible name of a global function gets an underscore prepended to it. You may have to take that into account when setting the breakpoint on such systems.

Now that you have set the MPATROL_OPTIONS environment variable and have set the debugger to break at __mp_trap(), all that is required is for you to run your program. Hopefully, the debugger should stop at __mp_trap(). If it doesn't then you may have to check your environment variable settings to ensure that they are the same as when you ran the program outwith the debugger, although obviously with the addition of 'ALLOCSTOP', etc. Once the program has been halted by the debugger, you can then single-step through your code until you see where it goes wrong. If this is near the end of your program then you'll have saved yourself a lot of time by using this method.

The following example will be used to illustrate the steps involved in using the 'ALLOCSTOP', 'REALLOCSTOP' and 'FREESTOP' options. However, it is only for tutorial purposes and the same effect could easily be achieved by breaking at line 18 in a debugger because in this case it is obvious from the code and the mpatrol log file where it is going wrong. In real programs this is hardly ever the case[6].

```
1  /*
2   * Allocates 1000 blocks of 16 bytes, freeing each block immediately
```

[5] Unless you've linked the debugger with the mpatrol library.

[6] The other reason that this program is simple is because a proper example would generally involve crashing the program, but on AmigaOS and Netware that would also involve crashing the system — not something you'd want to do whilst trying this out.

```
 3   * after it is allocated, and freeing the last block twice.
 4   */

 7  #include "mpatrol.h"

10  int main(void)
11  {
12      void *p;
13      int i;

15      for (i = 0; i < 1000; i++)
16          if (p = malloc(16))
17              free(p);
18      free(p);
19      return EXIT_SUCCESS;
20  }
```

Compile this example code with debugging information enabled and link it with the mpatrol library, then set `MPATROL_OPTIONS` to '`LOGALL`' and run the resulting program. If you examine '`mpatrol.log`' you will see the following near the bottom of the file.

```
...

ALLOC: malloc (1000, 16 bytes, 2 bytes) [main|test.c|16]
        0x80000D8E main
        0x80000D24 _start

returns 0x80033000

FREE: free (0x80033000) [main|test.c|17]
        0x80000DBE main
        0x80000D24 _start

    0x80033000 (16 bytes) {malloc:1000:0} [main|test.c|16]
        0x80000D8E main
        0x80000D24 _start

FREE: free (0x80033000) [main|test.c|18]
        0x80000DE8 main
        0x80000D24 _start

ERROR: free: 0x80033000 has not been allocated

...
```

In this example, we'll want to use '`ALLOCSTOP`' to halt the program at the 1000th memory allocation so that we can step through it with a debugger. So, set `MPATROL_OPTIONS` to '`ALLOCSTOP=1000`' and load the program into the debugger. If you are using `gdb` you can now do the following steps, but if you are not you will have to use the equivalent commands

in your debugger. Note that '`(gdb)`' is the debugger command prompt and so anything that appears on that line after that should be typed as a command.

```
(gdb) break __mp_trap
Breakpoint 1 at 0x80004026
(gdb) run
Starting program: a.out
Breakpoint 1, 0x80004026 in __mp_trap()

which has no line number information.
17                  free(p);
(gdb) step
15          for (i = 0; i < 1000; i++)
(gdb) step
18          free(p);
(gdb) quit
The program is running.  Quit anyway (and kill it)? (y or n) y
```

After setting the breakpoint and running the program, the debugger halts at `__mp_trap()`. Because `__mp_trap()` is a function within the mpatrol library, you don't want to bother stepping through any of the library functions, and in this case you can't since the mpatrol library was not compiled with debugging information enabled. So, after returning from all of the library functions, the source line becomes line 16 because that was the location of the 1000th memory allocation. Single-stepping twice gets us to line 18 which is our destination.

7.6 Testing

The mpatrol library has several features that make it useful when testing a program's dynamic memory allocations. These are features that do not help in fixing an existing bug, but rather help to identify additional bugs that may be lurking in your code.

It is possible to set a simulated upper limit on the amount of heap memory available to a process with the '`LIMIT`' option, which accepts a size in bytes, but will be disabled when it is zero. This can be extremely useful for testing a program under simulated low memory

conditions to see how it handles such errors. Of course, you should set the heap limit to a value less than the amount of actual available memory otherwise this option will have no effect. Note that the mpatrol library may use up a small amount of heap memory when it initialises itself[7] so the value passed to the '`LIMIT`' option may need to be set slightly higher than you would normally expect.

It is also possible to instruct the mpatrol library to randomly fail a certain number of memory allocations so that you can further test error handling code in a program. The frequency at which failures occur can be controlled with the '`FAILFREQ`' option, where a value of zero means that no failures will occur, but any other value will randomly cause failures. For example, a value of '`10`' will cause roughly one in ten failures and a value of '`1`' will cause every memory allocation to fail. The random sequence can be made predictable by using the '`FAILSEED`' option. If this is non-zero then the same program run with the same failure frequency and same failure seed will fail on exactly the same memory allocations. If this is zero then the failure seed will itself be set randomly, but you can see its value when the summary is displayed at program termination.

When running *batch tests*[8] it is sometimes useful to be able to detect if there have been any memory leaks. Such leaks should normally be distinguished from code which has purposely not freed the memory that it allocated, so there may be a certain expected number of unfreed allocations at program termination. It may be that you would like to highlight any additional unfreed allocations since they may be due to real memory leaks, so the '`UNFREEDABORT`' option can be set to a threshold number of expected unfreed allocations. If the library detects a number of unfreed allocations higher than this then it will abort the program at termination so that it fails. All tests that fail in this way can then be examined after the test suite finishes.

7.7 Library functions

Along with the standard set of C and C++ dynamic memory allocation functions, the mpatrol library also comes with an additional set of functions which can be used to provide additional information to your program, and which can be called at various points in your code for debugging purposes. You must always include the '`mpatrol.h`' header file in order to use these functions, but you can check for a specific version of the mpatrol library by checking the `MPATROL_VERSION` preprocessor macro.

It is possible to obtain a great deal of information about an existing memory allocation using the `__mp_info()` function. This takes an address as an argument and fills in any details about its corresponding memory allocation in a supplied structure. The following example illustrates this (it can be found in '`tests/pass/test4.c`').

```
23  /*
24   * Demonstrates and tests the facility for obtaining information
25   * about the allocation a specific address belongs to.
26   */
```

[7] Actually, it's not really the mpatrol library that uses the memory but the object file access libraries since they call `malloc()` to allocate any memory that they require.

[8] A set of tests that run without user intervention.

```
29  #include "mpatrol.h"
30  #include <stdio.h>

33  void display(void *p)
34  {
35      __mp_allocstack *s;
36      __mp_allocinfo d;

38      if (!__mp_info(p, &d))
39      {
40          fprintf(stderr, "nothing known about address 0x%08lX\n", p);
41          return;
42      }
43      fprintf(stderr, "block:   0x%08lX\n", d.block);
44      fprintf(stderr, "size:    %lu\n", d.size);
45      fprintf(stderr, "type:    %lu\n", d.type);
46      fprintf(stderr, "alloc:   %lu\n", d.alloc);
47      fprintf(stderr, "realloc: %lu\n", d.realloc);
48      fprintf(stderr, "func:    %s\n", d.func ? d.func : "NULL");
49      fprintf(stderr, "file:    %s\n", d.file ? d.file : "NULL");
50      fprintf(stderr, "line:    %lu\n", d.line);
51      for (s = d.stack; s != NULL; s = s->next)
52      {
53          fprintf(stderr, "\t0x%08lX: ", s->addr);
54          fprintf(stderr, "%s\n", s->name ? s->name : "NULL");
55      }
56      fprintf(stderr, "freed:   %d\n", d.freed);
57  }

60  void func2(void)
61  {
62      void *p;

64      if (p = malloc(16))
65      {
66          display(p);
67          free(p);
68      }
69      display(p);
70  }

73  void func1(void)
74  {
75      func2();
76  }
```

```
79  int main(void)
80  {
81      func1();
82      return EXIT_SUCCESS;
83  }
```

When this is compiled and run, it should give the following output, although the pointers are likely to be different.

```
block:   0x8000A068
size:    16
type:    0
alloc:   10
realloc: 0
func:    func2
file:    test4.c
line:    64
         0x80000BEC: func2
         0x80000C3E: func1
         0x80000C48: main
         0x800009E8: _start
freed:   0
nothing known about address 0x8000A068
```

As you can see, anything that the mpatrol library knows about any memory allocation can be obtained for use in your own code, which can be very useful if you need to write handlers to keep track of memory allocations, etc. for debugging purposes.

It is also possible for you to be able to intercept calls to allocate, reallocate and deallocate memory for your own purposes. You can install prologue and epilogue functions that the mpatrol library will call before and after every time one of its functions is called. These can be used for additional tracing or simply to add extra checks to your code. The following code is an example of this and can be found in '`tests/pass/test2.c`'.

```
23  /*
24   * Demonstrates and tests the facility for specifying user-defined
25   * prologue and epilogue functions.
26   */

29  #include "mpatrol.h"
30  #include <stdio.h>

33  void prologue(void *p, size_t l)
34  {
35      if (p == (void *) -1)
36          fprintf(stderr, "allocating %lu bytes\n", l);
37      else if (l == (size_t) -1)
38          fprintf(stderr, "freeing allocation 0x%08lX\n", p);
39      else if (l == (size_t) -2)
40          fprintf(stderr, "duplicating string `%s'\n", p);
```

```
41      else
42          fprintf(stderr, "reallocating allocation 0x%08lX to %lu bytes\n", p, l);
43  }

46  void epilogue(void *p)
47  {
48      if (p != (void *) -1)
49          fprintf(stderr, "allocation returns 0x%08lX\n", p);
50  }

53  int main(void)
54  {
55      void *p, *q;

57      __mp_prologue(prologue);
58      __mp_epilogue(epilogue);
59      if (p = malloc(16))
60          if (q = realloc(p, 32))
61              free(q);
62          else
63              free(p);
64      if (p = (char *) strdup("test"))
65          free(p);
66      return EXIT_SUCCESS;
67  }
```

Once again, if you compile and run the above code, you should see the following output.

```
allocating 16 bytes
allocation returns 0x8000A068
reallocating allocation 0x8000A068 to 32 bytes
allocation returns 0x8000A068
freeing allocation 0x8000A068
duplicating string ‘test’
allocation returns 0x8000A068
freeing allocation 0x8000A068
```

Along with being able to install prologue and epilogue functions, you can also install a low-memory handler with the `__mp_nomemory()` function, which will be called by the mpatrol library if it ever runs out of memory during the call to a memory allocation function. This gives you the opportunity to use that handler to either free up any unneeded memory or simply to abort, thus removing the need to check for failed allocations.

Finally, there are three functions which affect the mpatrol library globally. The first, `__mp_check()`, allows you to force an internal check of the mpatrol library's data structures at any point during program execution. The other two functions, `__mp_memorymap()` and `__mp_summary()` allow you to force the generation of a memory map or library statistics at any point in your program, in much the same way as they would normally be displayed at the end of program execution.

7.8 Utilities

On UNIX platforms, a shell script is provided which can run programs that have been linked with the mpatrol library using a combination of mpatrol options that can be set via the command line. All of these options but one map directly onto their equivalent environment variable settings and exist mainly so that the user does not have to manually change the `MPATROL_OPTIONS` environment variable.

The one option that is the exception to this is the '`-d`' option, which can be used to run a program under the control of the mpatrol library, even if it wasn't originally linked with the mpatrol library. This can only be done on systems that support dynamic linking and where the dynamic linker recognises the `LD_PRELOAD` environment variable. Even then, it can only be used when the program that is being run has been dynamically linked with the system C library, rather than statically linked.

The reason for all of these limitations is that some SVR4 UNIX platforms have a special feature in the dynamic linker which can be told to override the symbols from one shared library using the symbols from another shared library at run-time. In this case, it involves replacing the symbols for `malloc()`, etc., in the system C library with the mpatrol versions, but only if they were marked as undefined in the original executable file and would therefore have to have been loaded from '`libc.so`'.

However, if a program qualifies for use with the '`-d`' option, it means that you can trace all of its dynamic memory allocations as well as running it with any of the mpatrol library's debugging options. This is mainly a *toy* feature which allows you to view and manipulate the dynamic memory allocations of programs that you don't have the source for, but in theory it could be quite useful if you need to debug a previously released executable and are unable to recompile or relink it.

Note that the `mpatrol` shell script must be set up to use the correct object file format access libraries that are required for your system if you wish to use the '`-d`' option. If the mpatrol library was built with `FORMAT=FORMAT_ELF32` support then it must be told to preload the ELF access library (normally '`libelf.so`'). If it was built with `FORMAT=FORMAT_BFD` support then it must be told to preload the GNU BFD access libraries (normally '`libbfd.so`' and '`libiberty.so`'). However, if these libraries only exist on your system in archive form then you must build '`libmpatrol.so`' with these extra libraries incorporated into it so that there are no dependencies on them at run-time. However, there may well be problems if the resulting shared library contains position-dependent code from the archive libraries you incorporated. The only way to find out is for you to try it and see.

8 Improving performance

Because of their need to cover every eventuality, malloc library implementations are very general and most do their job well when you consider what is thrown at them. However, your program may not be performing as well as it should simply because there may be a more efficient way of dealing with dynamic memory allocations. Indeed, there may even be a more efficient malloc library available for you to use.

If you need to allocate lots of blocks of the same size[1], but you won't know the number of blocks you'll require until run-time then you could take the easy approach by simply allocating a new block of memory for each occurrence. However, this is going to create a lot of (typically small) memory blocks that the underlying malloc library will have to keep track of, and even in many good malloc libraries this is likely to cause memory fragmentation and possibly even result in the blocks scattered throughout the address space rather than all in the one place, which is not necessarily a good thing on systems with virtual memory.

An alternative approach would be to allocate memory in multiples of the block size, so that several blocks would be allocated at once. This would require slightly more work on your part since you would need to write interface code to return a single block, while possible allocating space for more blocks if no free blocks were available. However, this approach has several advantages. The first is that the malloc library only needs to keep track of a few large allocations rather than lots of small allocations, so splitting and merging free blocks is less likely to occur. Secondly, your blocks will be scattered about less in the address space of the process, which means that on systems with virtual memory there are less likely to be page faults if you need to access or traverse all of the blocks you have created.

A memory allocation concept that is similar to this is called an *arena*. This datatype requires functions which are built on top of the existing malloc library functions and which associate each memory allocation with a particular arena. An arena can have as many allocations added to it as required, but allocations cannot usually be freed until the whole arena is freed. Note that there are not really any generic implementations of arenas that are available as everyone tends to write their own version when they require it, although SGI IRIX systems do come with an arena library called *amalloc*.

However, what if you don't plan to free all of the blocks at the same time? A slight modification to the above design could be to have a *slot table*. This would involve allocating chunks of blocks as they are required, adding each individual block within a chunk to a singly-linked list of free blocks. Then, as new blocks are required, the allocator would simply choose the first block on the free list, otherwise it would allocate memory for a new chunk of blocks and add them to the free list. Freeing individual blocks would simply involve returning the block to the free list. If this description isn't clear enough, have a look in '`src/slots.h`' and '`src/slots.c`'. This is how the mpatrol library allocates memory from the system for all of its internal structures. For variable-sized structures, a slightly different approach needs to be taken, but for an example of this using strings see '`src/strtab.h`' and '`src/strtab.c`'.

Another optimisation that is possible on UNIX and Windows platforms is making use of memory-mapped files. This allows you to map a filesystem object into the address space of your process, thus allowing you to treat a file as an array of bytes. Because it uses the

[1] Such as for use in a linked list.

virtual memory system to map the file, any changes you make to the mapped memory will be applied to the file. This is implemented through the virtual memory system treating the file as a pseudo swap file and will therefore only use up physical memory when pages are accessed. It also means that file operations can be replaced by memory read and write operations, leading to a very fast and efficient way of performing I/O. Another added bonus of this system means that entire blocks of process memory can be written to a file for later re-use, just as long as the file can later be mapped to the same address. This can be a lot faster than writing to and reading from a specific format of file.

If you really don't want to keep track of dynamic memory allocations at all then perhaps you should consider *garbage collection*. This allows you to make dynamic memory allocations that need not necessarily be matched by corresponding calls to free these allocations. A garbage collector will (at certain points during program execution) attempt to look for memory allocations that are no longer referenced by the program and free them for later re-use, hence removing all possibility of memory leaks. However, the garbage collection process can take a sizable chunk of processor time depending on how large the program is, so it is not really an option for real-time programming. It is also very platform-dependent as it examines very low-level structures within a process in order to determine which pointers point to which memory allocations. But there is at least one garbage collector[2] that works well with C and C++ and acts as a replacement for `malloc()` and `free()`, so it may be the ideal solution for you.

If you do choose to use an alternative malloc library make sure that you have a license to do so and that you follow any distribution requirements. On systems that support dynamic linking you may want to link the library statically rather than dynamically so that you don't have to worry about an additional file that would need to be installed. However, whether you have that choice depends on the license for the specific library, and some licenses also require that the source code for the library be made readily available. Shared libraries have the advantage that they can be updated with bug fixes so that all programs that require these libraries will automatically receive these fixes without needing to be relinked.

If all of the above suggestions do not seem to help and you still feel that you have a performance bottleneck in the part of your code that deals with dynamically allocated memory then you should try using a *memory profiler*[3]. This can be used at run-time to analyse the dynamic memory allocation calls that your program makes during its execution, and builds statistics for later viewing. It is then possible for you to see exactly how many calls were made to each function, where they came from and what proportion of time they each took. Such information can then be put to good use in order to optimise the relevant parts of your code.

And finally, some tips on how to correctly use dynamic memory allocations. The first, most basic rule is to *always* check the return values from `malloc()` and related functions. *Never* assume that a call to `malloc()` will succeed, because you're unlikely to be able to read the future[4]. Alternatively, use (or write) an `xmalloc()` or similar function, which calls `malloc()` but never returns '`NULL`' since it will abort instead. With the C++ operators it

[2] A freely distributably library called GC (see Appendix G [Related software], page 101).

[3] There is currently at least one memory profiler available (see Appendix G [Related software], page 101).

[4] If you can, why are you reading this — you've already read it!

is slightly different because some versions use exceptions to indicate failure, so you should always provide a handler to deal with this eventuality.

Never use *features*[5] of specific malloc libraries if you want your code to be portable. Always follow the ANSI C or C++ calling conventions and never make assumptions about the function or operator you are about to call — the standards committees went to great lengths to explicitly specify its behaviour. For example, don't assume that the contents of a freed memory allocation will remain valid until the next call to `malloc()`, and don't assume that the contents of a newly allocated memory block will be zeroed unless you created it with `calloc()`.

Finally, try stress-testing your program in low memory conditions. The mpatrol library contains the '`LIMIT`' option which can place an upper bound on the size of the heap, and also contains the '`FAILFREQ`' and '`FAILSEED`' options which can cause random memory allocation failures. Doing this will test parts of your code that you would probably never expect to be called, but perhaps they will one day! Who would you rather have debugging your program — yourself or the user?

[5] Whether they are documented or not.

9 How it works

The mpatrol library was originally written with the intention of plugging it into an existing compiler so that the compiler could plant calls to it in the code it generated when a specific debugging option was used. These extra calls would obviously slow the code down, but along with the stack checking options that would be provided, this would give the user an enhanced run-time debugging environment. Unfortunately, this integration never happened, but the way that mpatrol works is still significantly different from other malloc tracing libraries.

In order to quickly determine exactly which memory allocation a heap address belonged to it was necessary to be able to search the heap in an efficient manner. The traditional way of searching along a linked list was unfeasible, so an implementation based on *red-black trees* was used, where every known memory allocation in the heap was given an entry in the tree, with their start addresses as the key. Another major design decision was to also choose red-black trees to implement the *best fit* allocation algorithm. Although *first fit* was considered, I decided that best fit would allow the library to have more control over the heap, with every free memory block in the heap given an entry in the free tree, with their sizes as the key. There was a bit of work involved in getting the splitting and merging of free blocks to work efficiently, but it seems to work well now.

My original implementation had all of the information about each memory block stored just before the block itself. I eventually dropped that behaviour in favour of storing all of the library's internal information in a separate part of the heap. I did that for two reasons. The first was because of the problems that would occur due to memory allocations with different alignment requirements. The second reason was that the library's internal structures could be write-protected on systems with virtual memory, to prevent user code interfering with the operation of the library.

The library is written in a modular fashion so as to make it easy to add new functionality. New modules have already been added, such as the *stack* and *symbol* modules. Extra information about each memory allocation can be added to the *allocation information* module in '`src/info.h`' and '`src/info.c`' without having to change much code in any other files.

10 Examples

Following are a set of examples that are intended to illustrate what exactly is possible with the mpatrol library and how to go about using it effectively.

You should already have built and installed the library and should know how to link programs with the library. Unfortunately, it isn't possible to give specific instructions on how to do this as it varies from system to system and also depends on your preferred compiler and development tools.

However, on a typical SVR4 UNIX system, with mpatrol installed in '`/usr/local`', the mpatrol library can usually be incorporated into a program using the following commands:

- If the mpatrol library was built with no support for any object file format or was built with support for the COFF object file format:

```
cc -I/usr/local/include <file> -L/usr/local/lib -lmpatrol
```

- If the mpatrol library was built with support for the ELF32 object file format access library:

```
cc -I/usr/local/include <file> -L/usr/local/lib -lmpatrol -lelf
```

- If the mpatrol library was built with support for the GNU BFD object file format access library:

```
cc -I/usr/local/include <file> -L/usr/local/lib -lmpatrol -lbfd
   -liberty
```

If you need to link with other libraries, make sure that they don't contain definitions of `malloc()`, etc., or if they do then you must ensure that the mpatrol library appears before them on the link line.

You should also know how to set an environment variable on your specific system. Again, this varies from system to system and also depends on the command line interpreter or shell that you use. The environment variable that the mpatrol library uses is called `MPATROL_OPTIONS`. You can see exactly what options are available for this environment variable by setting it to '`HELP`' and then running a program that has been linked with the library.

10.1 Getting started

The first example we'll look at is when the argument in a call to `free()` doesn't match the return value from `malloc()`, even though the intention is to free the memory that was allocated by `malloc()`. This example is in '`tests/fail/test1.c`' and causes many existing `malloc()` implementations to crash.

Along the way, I'll try to describe as many features of the mpatrol library as possible, and illustrate them with examples. Note that the output from your version of the library is likely to vary slightly from that shown in the examples, especially on non-UNIX systems.

```
23  /*
24   * Allocates a block of 16 bytes and then attempts to free the
25   * memory returned at an offset of 1 byte into the block.
26   */
```

```
29  #include "mpatrol.h"

32  int main(void)
33  {
34      char *p;

36      if (p = (char *) malloc(16))
37          free(p + 1);
38      return EXIT_SUCCESS;
39  }
```

Note that I've removed the copyright message from the start of the file and added line numbers so that the tracing below makes more sense.

After compiling and linking the above program with the mpatrol library, the `MPATROL_OPTIONS` environment variable should be set to be '`LOGALL`' and the program should be executed, generating the following output in '`mpatrol.log`'.

```

ALLOC: malloc (13, 16 bytes, 8 bytes) [main|test1.c|36]
 (9) -> 0x00010AE0 main
        0x000109D4 _start <- (10)

returns 0x00028000 <- (11)
```

1. Allocation type. This generalises the type of dynamic memory operation that is being performed, and can be one of '`ALLOC`', '`REALLOC`' or '`FREE`'. This should make looking for all allocations, reallocations or frees in the log file a lot easier. Alternatively, if a memory operation function was called then this can also be one of '`MEMSET`', '`MEMCOPY`', '`MEMFIND`' or '`MEMCMP`'.
2. Allocation function. This is the name of the function that has been called to allocate the memory, in this case '`malloc`'.
3. Allocation index. This is incremented every time a new memory allocation is requested, and persists even if the memory allocation is resized with `realloc()`, `recalloc()` or `expand()`, so can be useful to keep track of a memory allocation, even if its start address changes. The mpatrol library may use up the first few allocation indices when it gets initialised.

4. Size of requested allocation.
5. Alignment for requested allocation. This is normally the default system alignment for general-purpose memory allocations, but may be different depending on the type of function that is used to allocate the memory.

The following information contains source file details of where the call to `malloc()` came from, but is only available if the source file containing the call to `malloc()` included '`mpatrol.h`'; otherwise the fields will all be '`-`'[1]. Because of the convoluted way this information is obtained for the C++ operators, you may encounter some problems in existing C++ programs when making direct calls to `operator new` for example. However, if you want to disable the redefinition of the C++ operators in '`mpatrol.h`' you can define the preprocessor macro `MP_NOCPLUSPLUS` before the inclusion of that file.

6. Function where call to `malloc()` took place. This information is only available if the source file containing the call to `malloc()` was compiled with `gcc` or `g++`.
7. Filename in which call to `malloc()` took place.
8. Line number at which call to `malloc()` took place.

The following information contains function call stack details of where the call to `malloc()` came from, but is only available if the mpatrol library has been built on a platform that supports this. The top-most entry should be the function which called `malloc()` and the bottom-most entry should be the entry-point for the process.

9. Address of function call. This is normally the address of the machine instruction immediately after the function call instruction, also known as the return address.
10. Function where call took place. This information is only available if the mpatrol library has been built on a platform that supports reading symbol table information from executable files, and then only if there is an entry in the symbol table corresponding to the return address. C++ function names may still be in their mangled form, but this can be easily rectified by processing the log file with a C++ name demangler.

The following information is only available when the allocation type is '`ALLOC`' or '`REALLOC`' since it makes no sense when applied to '`FREE`'.

11. The address of the new memory block that has been allocated by `malloc()`.

As you can see, there is quite a lot of information that can be displayed from a simple call to `malloc()`, and hopefully this information has been presented in a clear and concise format in the log file.

The next entries in the log file correspond to the call to `free()`, which attempts to free the memory allocated by `malloc()`, but supplies the wrong address.

The first three lines should be self-explanatory as they are very similar to those described above for `malloc()`. However, the next lines signal that a terminal error has occurred in the program, so I've annotated them as before.

```
FREE: free (0x00028001) [main|test1.c|37]
        0x00010B24 main
        0x000109D4 _start
```

[1] This information may also be filled in if the '`USEDEBUG`' option is used and supported, and if debugging information about the call to `malloc()` is available.

```
 (1)   (2)
  |     |
  V     V
ERROR: free: 0x00028001 does not match allocation of 0x00028000

        V          V         V    V  V    V      V    V
   0x00028000 (16 bytes) {malloc:13:0} [main|test1.c|36]
(11) -> 0x00010AE0 main
        0x000109D4 _start
```

1. Error severity. The mpatrol library has two different severities of error: '`WARNING`' and '`ERROR`'. The first is always recoverable, and serves only to indicate that something is not quite right, and so may be useful in determining where something started to go wrong. The second may or may not be recoverable, and the library terminates the program if it is fatal, displaying any relevant information as it does this.
2. Allocation function. This is the name of the function used to allocate, reallocate or free memory where the error was detected. This may be omitted if an error is detected elsewhere in the library.

The following information is related to the information that the library has stored about the relevant memory allocation. This information is always displayed in this format when details of individual memory allocations are required. If any information is missing then it simply means that the library was not able to determine it when the memory block was first allocated.

3. Address of memory allocation.
4. Size of memory allocation.
5. Allocation function. This is the name of the function that was called to allocate the memory block, in this case '`malloc`'. If the memory allocation has been resized then this will be either '`realloc`', '`recalloc`' or '`expand`'.
6. Allocation index.
7. Reallocation index. This is used to count the number of times a memory allocation has been resized with `realloc()`, `recalloc()` or `expand()`.
8. Function where original call to `malloc()` took place. If the memory allocation has been resized then this will be the name of the function which last called `realloc()`, `recalloc()` or `expand()`.
9. Filename in which original call to `malloc()` took place. If the memory allocation has been resized then this will be the filename in which the last call to `realloc()`, `recalloc()` or `expand()` took place.
10. Line number at which original call to `malloc()` took place. If the memory allocation has been resized then this will be the line number at which the last call to `realloc()`, `recalloc()` or `expand()` took place.
11. Function call stack of original memory allocation. If the memory allocation has been resized then this will be the call stack of the last call to `realloc()`, `recalloc()` or `expand()`.

So, the mpatrol library detected the error in the above program and terminated it. When the library terminates it always displays a summary of various memory allocation statistics and settings that were used during the execution of the program.

The various settings and statistics displayed by the library for the above example have been numbered and their descriptions appear below.

```
 1  system page size:  8192 bytes
 2  default alignment: 8 bytes
 3  overflow size:     0 bytes
 4  overflow byte:     0xAA
 5  allocation byte:   0xFF
 6  free byte:         0x55
 7  allocation stop:   0
 8  reallocation stop: 0
 9  free stop:         0
10  unfreed abort:     0
11  lower check range: -
12  upper check range: -
13  failure frequency: 0
14  failure seed:      533453
15  prologue function: <unset>
16  epilogue function: <unset>
17  handler function:  <unset>
18  log file:          mpatrol.log
19  program filename:  /proc/729/object/a.out
20  symbols read:      3240
21  allocation count:  13
22  allocation peak:   4720 bytes
23  allocation limit:  0 bytes
24  allocated blocks:  1 (16 bytes)
25  freed blocks:      0 (0 bytes)
26  free blocks:       1 (8176 bytes)
27  internal blocks:   25 (204800 bytes)
28  total heap usage:  212992 bytes
29  total compared:    0 bytes
30  total located:     0 bytes
31  total copied:      0 bytes
32  total set:         0 bytes
33  total warnings:    0
34  total errors:      1
```

1. System page size. This value is used on some platforms when allocating and protecting system memory.
2. Default alignment. This value is the minimum alignment required for general purpose memory allocations, and is usually the alignment required by the most restrictive datatype on a given system. It is used when allocating memory that has no specified alignment. It can be changed at run-time using the '`DEFALIGN`' option, but setting this value too small may cause the program to crash due to bus errors which are caused by reading from or writing to misaligned data.

3. Overflow size. This value is the size used by one overflow buffer. If this is non-zero then every memory allocation will have two overflow buffers; one on either side. These buffers are used by the library to detect if the program has written too many bytes to a memory allocation, thus overflowing into one of the buffers, but these extra checks can slow down execution speed. It can be changed at run-time using the '`OFLOWSIZE`' option.
4. Overflow byte.
5. Allocation byte.
6. Free byte. These values are used by the library to pre-fill blocks of memory for checking purposes. The overflow byte is used to fill overflow buffers, the allocation byte is used to fill newly-allocated memory (except from `calloc()` or `recalloc()`), and the free byte is used to fill free blocks or freed memory allocations. These can be changed at run-time using the '`OFLOWBYTE`', '`ALLOCBYTE`' and '`FREEBYTE`' options.
7. Allocation stop.
8. Reallocation stop.
9. Free stop. These values are used by the library to halt the program when run inside a debugger whenever a specified allocation index is allocated, reallocated or freed. These can be changed at run-time using the '`ALLOCSTOP`', '`REALLOCSTOP`' and '`FREESTOP`' options.
10. Unfreed abort. This value is used when the program terminates and is used by the library to check if there are more than a given number of unfreed memory allocations. If there are then the library will cause the program to abort with an error. It can be changed at run-time using the '`UNFREEDABORT`' option.
11. Lower check range.
12. Upper check range. These values specify the range of allocation indices through which the library will physically check every area of free memory and every overflow buffer for errors. A dash specifies that either the lower or upper range is infinite, but if they are both zero then no such checking will ever be performed, thus speeding up execution speed dramatically. The library defaults to performing checks for every allocation index. These can be changed at run-time using the '`CHECK`' option.
13. Failure frequency.
14. Failure seed. These values are used to specify if random memory allocation failures should occur during program execution, for the purposes of stress testing a program. If the failure frequency is zero then no random failures will occur, but if it is greater than zero then the higher the number, the less frequent the failures. The failure seed is used internally by the mpatrol library when generating random numbers. If it is zero then the seed will be set randomly, but if it is greater than zero then it will be used to generate a predictable sequence of random numbers; i.e. two runs of the same program with the same failure frequencies and the same failure seeds will generate exactly the same sequence of failures.
15. Prologue function.
16. Epilogue function.
17. Handler function. These values contain addresses or names of functions that have been installed as callback functions for the library. These functions, if set, will be called

from the library at appropriate times during program execution in order to handle specific events. These can be changed at compile-time using the `__mp_prologue()`, `__mp_epilogue()` and `__mp_nomemory()` functions.

18. Log file. Simply contains the name of the file where all mpatrol library diagnostics go to. It can be changed at run-time using the '`LOGFILE`' option.
19. Program filename. Contains the full pathname to the program's executable file. This is used by the mpatrol library to read the symbol table in order to provide symbolic information in function call stacks. It can be changed at run-time using the '`PROGFILE`' option.
20. Symbols read. This value contains the total number of symbols read from a program's executable file and/or the dynamic linker, if applicable.
21. Allocation count. This value contains the total number of memory allocations that were created by the mpatrol library. This value may be more than expected if the mpatrol library makes any memory allocations during initialisation.
22. Allocation peak. This value contains the peak memory usage set by the program when running. This value may be more than expected if the mpatrol library makes any memory allocations during initialisation.
23. Allocation limit. This value is used to limit the amount of memory that can be allocated by a program, which can be useful for stress-testing in simulated low memory conditions. It can be changed at run-time using the '`LIMIT`' option.
24. Allocated blocks.
25. Freed blocks.
26. Free blocks. These values contain the total number of allocated, freed and free blocks at the time the summary was produced. A freed block is an allocated block that has been freed but has not been returned to the free memory list for later allocation. These values may be different from those expected if the mpatrol library makes any memory allocations during initialisation.
27. Internal blocks. This value contains the total number of memory blocks (of varying sizes) that have been allocated from the system for the mpatrol library to use internally. These memory blocks will be write-protected on systems that support memory protection in order to prevent the program from corrupting the library's data structures. This can be overridden at run-time using the '`NOPROTECT`' option in order to speed up program execution slightly.
28. Total heap usage. This value contains the total amount of system heap memory that has been allocated by the mpatrol library.
29. Total compared.
30. Total located.
31. Total copied.
32. Total set. These values contain the total number of bytes that have been tracked by the mpatrol library in byte comparison operations (such as `memcmp()`), byte location operations (such as `memchr()`, byte copy operations (such as `memcpy()`) and byte set operations (such as `memset()`) respectively. They do not take into account any other such operations that occur outwith these functions, such as loading and storing from machine instructions.

33. Total warnings.
34. Total errors. The library keeps a count of the total number of warnings and errors it has displayed so that you can quickly work out this information at program termination.

10.2 Detecting incorrect reuse of freed memory

The next example uses '`tests/fail/test2.c`' to illustrate how the mpatrol library can detect whereabouts on the heap an address belongs.

```
23  /*
24   * Allocates a block of 16 bytes and then immediately frees it.  An
25   * attempt is then made to double the size of the original block.
26   */

29  #include "mpatrol.h"

32  int main(void)
33  {
34      char *p;

36      if (p = (char *) malloc(16))
37      {
38          free(p);
39          p = (char *) realloc(p, 32);
40      }
41      return EXIT_SUCCESS;
42  }
```

The relevant excerpts from '`mpatrol.log`' appear below. The format of the log messages should be familiar to you now.

```
ALLOC: malloc (13, 16 bytes, 8 bytes) [main|test2.c|36]
        0x00010B18 main
        0x00010A0C _start

returns 0x00028000

FREE: free (0x00028000) [main|test2.c|38]
        0x00010B54 main
        0x00010A0C _start

    0x00028000 (16 bytes) {malloc:13:0} [main|test2.c|36]
        0x00010B18 main
        0x00010A0C _start

REALLOC: realloc (0x00028000, 32 bytes, 8 bytes) [main|test2.c|39]
        0x00010B88 main
        0x00010A0C _start
```

```
ERROR: realloc: 0x00028000 has not been allocated

returns 0x00000000
```

The mpatrol library stores all of its information about allocated and free memory in tree structures so that it can quickly determine if an address belongs to allocated or free memory, or if it even exists in the heap that is managed by mpatrol. The above example should illustrate this since after the allocation had been freed, the library recognised this and reported an error. It was possible for the program to continue execution even after that error since mpatrol could recover from it and return '`NULL`'.

It is possible for mpatrol to give even more useful diagnostics in the above situation by using the '`NOFREE`' option. This prevents the library from returning any freed allocations to the free memory pool, by preserving any information about them and marking them as freed. If you add the '`NOFREE`' option to the `MPATROL_OPTIONS` environment variable you should see the following entries in '`mpatrol.log`' instead.

```
ALLOC: malloc (13, 16 bytes, 8 bytes) [main|test2.c|36]
        0x00010B18 main
        0x00010A0C _start

returns 0x00029DE0

FREE: free (0x00029DE0) [main|test2.c|38]
        0x00010B54 main
        0x00010A0C _start

    0x00029DE0 (16 bytes) {malloc:13:0} [main|test2.c|36]
        0x00010B18 main
        0x00010A0C _start

REALLOC: realloc (0x00029DE0, 32 bytes, 8 bytes) [main|test2.c|39]
        0x00010B88 main
        0x00010A0C _start

ERROR: realloc: 0x00029DE0 was freed with free
    0x00029DE0 (16 bytes) {free:13:0} [main|test2.c|38]
        0x00010B54 main
        0x00010A0C _start

returns 0x00000000
```

Note the extra information reported by `realloc()` since the library knows all of the details about the freed memory allocation and when it was freed.

The '`NOFREE`' option tends to use up much more system memory than normal since it effectively instructs the mpatrol library to allocate new memory for every single memory allocation or reallocation. It can also slow down program execution when overflow buffers are used, since with each new memory allocation the library needs to check more and more overflow buffers every time it is called. However, it can be quite useful for problems such as this one. The test in '`tests/fail/test3.c`' has a similar situation.

Normally, the 'NOFREE' option will cause the library to fill all freed memory allocations with the free byte. However, the original contents of such allocations can be preserved with the 'PRESERVE' option. This could help in situations when you need to determine exactly if a program is relying on the contents of freed memory.

10.3 Detecting use of free memory

This next example illustrates how the mpatrol library is able to check to see if anything has been written into free memory. The test is located in 'tests/fail/test4.c' and simply writes a single byte into free memory.

```
23  /*
24   * Allocates a block of 16 bytes and then immediately frees it.  A
25   * NULL character is written into the middle of the freed memory.
26   */

29  #include "mpatrol.h"

32  int main(void)
33  {
34      char *p;

36      if (p = (char *) malloc(16))
37      {
38          free(p);
39          p[8] = '\0';
40      }
41      return EXIT_SUCCESS;
42  }
```

The following output was produced as part of 'mpatrol.log'. Note that this test was run using the same MPATROL_OPTIONS settings as the last example, but make sure that 'PRESERVE' is not set.

```
ERROR: freed allocation 0x00029DE0 has memory corruption at 0x00029DE8
        0x00029DE8  00555555 55555555                     .UUUUUUU

    0x00029DE0 (16 bytes) {free:13:0} [main|test4.c|38]
        0x00010B1C main
        0x000109D4 _start
```

The library was able to detect that something had been written into free memory and could report on the memory allocation that was overwritten. However, these checks are only performed whenever a function in the mpatrol library is called. In the example above, the code which wrote into free memory could have been miles away from where the library detected the error.

On platforms that support memory protection, the library also supports the 'PAGEALLOC' option. This option instructs the library to force every single memory allocation to have a size which is a multiple of the system page size. Although the library still stores the original

requested size, it effectively means that no two memory allocations occupy the same page of memory. It can then use page protection (which only operates on pages of memory) to protect all free memory from being read from or written to, and uses similar features to install a page of overflow buffer on either side of the allocation.

However, if the requested size for the memory allocation was not a multiple of the page size this means that there will still be unused space left over in the allocated pages. This problem is solved by turning the unused space into overflow buffers that will be checked in the normal way. The positioning of the allocation within its pages is also important. If you want to check for illegal reads from the borders of the memory allocation, unless it fits exactly into its pages then there is a chance that a program could illegally read the right-most overflow buffer if the allocation was left-aligned, or vice-versa. Two settings therefore exist for the '`PAGEALLOC`' option: '`LOWER`' and '`UPPER`'. They refer to the placement of every memory allocation within its constituent pages.

The following diagram illustrates the '`PAGEALLOC`' option. In the diagram, the system page size is assumed to be 16 bytes (very unlikely, but will serve for this example) and each character represents 1 byte.

```
x = allocated memory
o = overflow buffer (filled with the overflow byte)
. = overflow buffer page (read and write protected)

PAGEALLOC=LOWER, allocation size is 16 bytes or
PAGEALLOC=UPPER, allocation size is 16 bytes:
    ................xxxxxxxxxxxxxxxx................

PAGEALLOC=LOWER, allocation size is 8 bytes:
    ................xxxxxxxxoooooooo................

PAGEALLOC=UPPER, allocation size is 8 bytes:
    ................ooooooooxxxxxxxx................
```

In our original example, if the '`PAGEALLOC=LOWER`' option is added to the `MPATROL_OPTIONS` environment variable then the following error will be produced instead of the original error.

```
ERROR: illegal memory access at address 0x0009E008
    0x0009E000 (16 bytes) {free:13:0} [main|test4.c|38]
        0x00010B1C main
        0x000109D4 _start

    call stack
        0x00010B1C main
        0x000109D4 _start
```

On systems that support memory protection, the mpatrol library has a built-in signal handler which catches illegal memory accesses and terminates the program. In the above case, the freed memory was made write-protected and so could not be written to. The underlying virtual memory system in the operating system noticed this and signaled this to the library immediately after it happened.

Along with the details of the freed memory allocation that was being written to, the library also attempts to display the function call stack for the location in the program that

caused the illegal memory access, although this can be quite unreliable. A better solution would be to run the program in a debugger to catch the illegal memory access.

Note that the '`PAGEALLOC`' option also modifies the behaviour of the '`NOFREE`' and '`PRESERVE`' options when used together. The memory allocation being freed will always be made write-protected when the '`PRESERVE`' option is used, otherwise it will also be made read-protected to prevent further accesses.

Note also that the '`PAGEALLOC=UPPER`' option is potentially much less efficient at catching illegal memory accesses than the '`PAGEALLOC=LOWER`' option. This is due to alignment requirements, since an allocation of 1 byte requiring an alignment of 16 bytes cannot be placed at the very end of a page of size 4096 bytes. The following diagram illustrates this, using the same page size as the last diagram.

```
x = allocated memory
o = overflow buffer (filled with the overflow byte)
. = overflow buffer page (read and write protected)

PAGEALLOC=UPPER, allocation size is 16 bytes, alignment is 8 bytes:
    ................xxxxxxxxxxxxxxxx................

PAGEALLOC=UPPER, allocation size is 3 bytes, alignment is 1 byte:
    ................oooooooooooooxxx................

PAGEALLOC=UPPER, allocation size is 3 bytes, alignment is 8 bytes:
    ................ooooooooxxxooooo................
```

Everything is OK until the last allocation, where the alignment requirement means that there must be two overflow buffers. This slows down program execution since the library must check an additional overflow buffer, and also means that the program would have to read six bytes beyond the end of the allocation before the illegal memory access would be detected.

10.4 Using overflow buffers

This example illustrates the use of overflow buffers and so the `MPATROL_OPTIONS` environment variable should have '`OFLOWSIZE=2`' added to it. However, turn off any '`PAGEALLOC`' options for the purposes of this example. The test is located in '`tests/fail/test5.c`', and '`tests/fail/test6.c`' is very similar.

```
23  /*
24   * Allocates a block of 16 bytes and then copies a string of 16
25   * bytes into the block.  However, the string is copied to 1 byte
26   * before the allocated block which writes before the start of the
27   * block.  This test must be run with an OFLOWSIZE greater than 0.
28   */

31  #include "mpatrol.h"

34  int main(void)
```

```
35  {
36      char *p;

38      if (p = (char *) malloc(16))
39      {
40          strcpy(p - 1, "this test fails!");
41          free(p);
42      }
43      return EXIT_SUCCESS;
44  }
```

The following error should be produced in '`mpatrol.log`'.

```
ERROR: allocation 0x00029E28 has a corrupted overflow buffer at 0x00029E27
        0x00029E26  AA74                                    t

    0x00029E28 (16 bytes) {malloc:13:0} [main|test5.c|38]
        0x00010B0C main
        0x00010A00 _start
```

Once again, the library attempts to show you as much detail as possible about where the corruption occurred. Along with showing you a memory dump of the overflow buffer that was corrupted, it also shows you the allocation to which the overflow buffer belongs.

Using overflow buffers can reduce the speed of program execution since the library has to check every buffer whenever it is called, and if the buffers are larger then they'll take longer to check and will use up more memory. However, larger buffers mean that there is less chance of the program writing past one memory allocation into another.

Alternatively, the '`CHECK`' option can be used to limit the number of checks that the library has to perform, thus speeding up program execution. This option specifies a range of allocation indices through which the library will check overflow buffers and free memory for corruption. Such checks occur when they normally would, but only if the current allocation index falls within the specified range. This feature can be used when there is a suspicion that free memory corruption or overflow buffer corruption occurs at a certain point during program execution, but checking them at every library call would take too long.

On systems which support software watch points, there is an extra option called '`OFLOWWATCH`' which allows additional memory protection. Watch points allow individual bytes to be read and/or write protected as opposed to just pages. The '`OFLOWWATCH`' option installs software watch points at every overflow buffer instead of requiring the library to check the integrity of the overflow buffers, and can be used in combination with '`PAGEALLOC`'. However, software watch points slow down program execution to a crawl since every machine instruction must be checked individually by the system to see if it accesses a watch point area. Slowing the program down by a factor of 10,000 is not uncommon on some systems when the '`OFLOWWATCH`' option is used.

10.5 Bad memory operations

In C there are several basic memory operation functions that are often called to perform tasks such as clearing memory, copying memory, etc. The mpatrol library contains replacements for these which allow for better checking of their arguments to prevent reading and

writing past the boundaries of existing memory allocations. The following source can be found in 'tests/fail/test9.c'.

```
23  /*
24   * Allocates a block of 16 bytes and then attempts to zero the contents of
25   * the block.  However, a zero byte is also written 1 byte before and 1
26   * byte after the allocated block, resulting in an error in the log file.
27   */

30  #include "mpatrol.h"

33  int main(void)
34  {
35      char *p;

37      if (p = (char *) malloc(16))
38      {
39          memset(p - 1, 0, 18);
40          free(p);
41      }
42      return EXIT_SUCCESS;
43  }
```

When this is compiled and run, the following should appear in the log file.

```
ERROR: memset: range [0x00027FFF,0x00028010] overflows [0x00028000,0x0002800F]
    0x00028000 (16 bytes) {malloc:13:0} [main|test9.c|37]
        0x00010B18 main
        0x00010A0C _start
```

As you can see, the library detected that the `memset()` function would have written past the boundaries of the memory allocation and reported this to you. It then proceeded to ignore the request to copy the memory and continued with the execution of the program. Note that this will only be done for known memory allocations. Reading and writing past the boundaries of static and stack memory allocations cannot be detected in this way.

If the 'LOGMEMORY' option is added to the `MPATROL_OPTIONS` environment variable then it is possible to see a log of all the mpatrol library memory operation functions that were called during program execution. For example, adding this option and running the above program again will produce something similar to the following.

```
MEMSET: memset (0x00027FFF, 18 bytes, 0x00) [main|test9.c|39]
        0x00010B18 main
        0x00010A0C _start
```

This is similar to the tracing produced for memory allocation functions, except that the arguments in parentheses mean different things. For 'MEMSET', the first argument represents the start of the memory block to set, the second argument represents the number of bytes to set and the third argument represents the actual byte to set.

For 'MEMCOPY', the first argument represents the source memory block, the second argument represents the destination memory block and the third argument represents the number of bytes to copy. This is similar for 'MEMCMP'.

For ‘MEMFIND’, the first and second arguments represent the source memory block and its length, while the third and fourth arguments represent the memory block to search for and its length. In the implementation for `memchr()`, the byte to search for is copied to a one byte buffer and the address of that buffer is used as the memory block to search for.

Note that as with the memory allocation functions, ‘MEMCMP’, ‘MEMFIND’, ‘MEMCOPY’ and ‘MEMSET’ are used to generalise the types of operations being performed and are followed by the names of the actual functions being used. In some cases the functions may use a different ordering of parameters than that shown.

10.6 Incompatible function calls

This example illustrates how the mpatrol library checks for calls to incompatible pairs of memory allocation functions. It requires the use of C++, although does not use any C++ features except for overloaded operators. The source is in ‘tests/fail/test7.c’, and ‘tests/fail/test8.c’ is similar.

```
23  /*
24   * Allocates a block of 16 bytes using C++ operator new[] and then
25   * attempts to free it using C++ operator delete.
26   */

29  #include "mpatrol.h"

32  int main(void)
33  {
34      char *p;

36      p = new char[16];
37      delete p;
38      return EXIT_SUCCESS;
39  }
```

The relevant parts of ‘mpatrol.log’ are shown below.

```
ALLOC: operator new[] (17, 16 bytes, 8 bytes) [int main()|test7.c|36]
        0x00010A28 __builtin_vec_new
        0x00010ADC main
        0x000108D0 _start

returns 0x00028000

FREE: operator delete (0x00028000) [int main()|test7.c|37]
        0x00010A74 __builtin_delete
        0x00010AF0 main
        0x000108D0 _start

ERROR: operator delete: 0x00028000 was allocated with operator new[]
    0x00028000 (16 bytes) {operator new[]:17:0} [int main()|test7.c|36]
        0x00010A28 __builtin_vec_new
```

```
        0x00010ADC main
        0x000108D0 _start
```

This shows a call to `operator new[]`, closely followed by a call to `operator delete`. However, in C++ calls to `operator new[]` must be matched by calls to `operator delete[]` and not `operator delete`. Hence, the library reports this as an error and does not free the memory allocation.

10.7 Additional useful information

This last example illustrates the various '`SHOW`' options that are available for displaying additional information from the mpatrol library at program termination. It also shows how to easily detect memory leaks. Use the '`OFLOWSIZE=16`', '`NOFREE`' and '`SHOWALL`' options in `MPATROL_OPTIONS` before running.

```
 1  /*
 2   * Introduces a memory leak by clobbering a pointer with a new
 3   * memory allocation.  Use with SHOWUNFREED to display it.
 4   */

 7  #include "mpatrol.h"

10  int main(void)
11  {
12      void *p;

14      p = malloc(4);
15      p = malloc(4);
16      if (p != NULL)
17          free(p);
18      return EXIT_SUCCESS;
19  }
```

The information that we are interested in comes after the summary of library statistics generated in the log file. The first block of data shows a memory map of the heap that is being handled by mpatrol. This can be used to see graphically where a particular allocation is located, or to look for memory fragmentation. The '`SHOWMAP`' option also displays this information.

Note that gaps in the memory map can either be due to space used by internal memory blocks or to some other memory allocation library using up space. On some systems that don't have virtual memory, gaps are likely to be owned by other processes or belong to the system free memory list.

```
memory map:
  / 0x8000A000-0x8000A00F overflow (16 bytes)
 |+ 0x8000A010-0x8000A077 allocated (104 bytes) {malloc:1:0} [-|-|-]

    -------------------- gap (106496 bytes)
  / 0x8002D000-0x8002D00F overflow (16 bytes)
 |+ 0x8002D010-0x8002DBBF freed (2992 bytes) {free:9:0} [-|-|-]
  \ 0x8002DBC0-0x8002DBCF overflow (16 bytes)
--- 0x8002DBD0-0x8002DFFF free (1072 bytes)
```

The next block of data shows a summary of all the symbols that could be read from the program's executable file and/or any shared libraries that the program requires. This can be useful to see which symbols have actually been read by the mpatrol library. The '`SHOWSYMBOLS`' option also displays this information.

Note that the following data has been dramatically cut down in size for the purposes of this example. The '`...`' marks text that has been removed.

```
symbols read: 2438
    0x8000076C-0x800007D9 _init [/proc/789/exe] (110 bytes)
    0x80000900-0x8000094F _start [/proc/789/exe] (80 bytes)
    0x80000950-0x8000096F __do_global_dtors_aux [/proc/789/exe] (32 bytes)
    0x80000970-0x80000977 fini_dummy [/proc/789/exe] (8 bytes)
    ...
    0x80003B24-0x80003B4B __clear_cache [/proc/789/exe] (40 bytes)
```

```
0x80003B4C-0x80003B6F __do_global_ctors_aux [/proc/789/exe] (36 bytes)
0x80003B70-0x80003B77 init_dummy [/proc/789/exe] (8 bytes)
0x80003B78-0x80003BA9 _fini [/proc/789/exe] (50 bytes)
0xC0002604-0xC0002609 _start [/lib/ld.so.1] (6 bytes)

...
0xC008F8BC-0xC008FA4D __moddi3 [/lib/libc.so.6] (402 bytes)
0xC008FA50-0xC008FB19 __udivdi3 [/lib/libc.so.6] (202 bytes)
0xC008FB1C-0xC008FC1B __umoddi3 [/lib/libc.so.6] (256 bytes)
0xC008FC1C-0xC008FC4D _fini [/lib/libc.so.6] (50 bytes)
```

The next block of data shows a summary of all freed memory allocations. This is only possible because the '`NOFREE`' option was also given, otherwise there would be no details on freed memory allocations. All of these entries show where the allocation was freed, which can be useful if you quickly needed to see where an allocation was freed. The '`SHOWFREED`' option also displays this information.

As this example was run on UNIX, the mpatrol library replaces the default implementations of `malloc()`, `free()`, etc. As can be seen below, this allows the library to trace all calls to allocate dynamic memory in a process, even from functions that were not compiled with mpatrol. The two functions shown below were called by the mpatrol library in order to read the symbols from ELF object files. However, they are located in the ELF access library which was not compiled with mpatrol.

Note that the following data has again been cut down in size for the purposes of this example. The '`...`' marks text that has been removed.

```
freed allocations: 9 (15740 bytes)
    0x8000A098 (126 bytes) {free:2:0} [-|-|-]
        0x800011BC elf_end
        0xC0019668 __mp_init
        0xC001982A __mp_alloc
```

```
        0x8000099C main
        0x80000944 _start

    0x8000A136 (3536 bytes) {free:3:0} [-|-|-]
        0x8000104E _elf_free
        0xC0019668 __mp_init
        0xC001982A __mp_alloc
        0x8000099C main
        0x80000944 _start

    ...
```

The final block of data shows a summary of all unfreed memory allocations. This can show up memory leaks, although the first unfreed memory allocation in this example comes from the standard C library. On systems such as UNIX it does not really matter about these unfreed allocations since they will automatically be returned to the system on process termination.

However, the second unfreed allocation shows an example of a memory leak, where no pointers referencing that allocation remain in the program to free it with. If this was within a loop then the program could quickly run away with memory, causing at least a decrease in performance, and at most a memory shortage. The mpatrol library makes it easier to spot memory leaks.

The '`SHOWUNFREED`' option also displays this information.

```
unfreed allocations: 2 (108 bytes)
    0x8000A010 (104 bytes) {malloc:1:0} [-|-|-]
        0xC0052B4A _IO_fopen
        0xC0017A0C __mp_openlogfile
        0xC0019648 __mp_init
        0xC001982A __mp_alloc
        0x8000099C main
        0x80000944 _start

    0x8000AFC4 (4 bytes) {malloc:10:0} [main|test.c|14]
        0x8000099C main
        0x80000944 _start
```

11 Tutorial

In this chapter we'll look at a real example of using the mpatrol library to debug a program. All of the following building and debugging steps were performed on a Linux/m68k machine so the details may differ slightly on your system, but the concepts should remain the same. However, on systems without virtual memory some of the steps may actually cause the machine to lock up or crash so be aware of this if you are running such a system — you may be safer just reading this tutorial rather than attempting it!

This tutorial will also make use of the option '`USEDEBUG`' which displays source-level file names and line numbers associated with symbols in call stack tracebacks, but only if the underlying object file access library supports reading line tables from object files and even then only if the object files were compiled with debugging information enabled.

The program we are going to look at is a simple filter which processes its standard input and displays the processed information on its standard output. In this case the program converts all lowercase characters to uppercase and removes any blank lines. The source for the program is given below, but can also be found in '`tests/tutorial/test1.c`'.

```
23  /*
24   * Reads the standard input file stream, converts all lowercase
25   * characters to uppercase, and displays all non-empty lines to the
26   * standard output file stream.
27   */

30  #include <stdio.h>
31  #include <stdlib.h>
32  #include <string.h>
33  #include <ctype.h>

36  char *strtoupper(char *s)
37  {
38      char *t;
39      size_t i, l;

41      l = strlen(s);
42      t = (char *) malloc(l);
43      for (i = 0; i < l; i++)
44          t[i] = toupper(s[i]);
45      t[i] = '\0';
46      return t;
47  }

50  int main(void)
51  {
52      char *b, *s;

54      b = malloc(BUFSIZ);
```

```
55      while (gets(b))
56      {
57          s = strtoupper(b);
58          if (*s != '\0')
59          {
60              puts(s);
61              free(s);
62          }
63      }
64      free(b);
65      return EXIT_SUCCESS;
66  }
```

If you quickly skimmed over the above code then you might have noticed some rather obvious errors, but there are also some less obvious ones hidden there as well. After compiling and linking with the system C compiler and libraries it successfully runs, even when its source code is piped to it. So if it runs, why bother trying to debug it?

The short answer to that is that this program does in fact contain one rather major error that is likely to prevent it from running portably on other systems. However, for the purposes of this tutorial, we'll pretend that we've just been handed the source code for this program and have not worked on it before. So let's now try to compile and link it with the mpatrol library[1].

First, add the inclusion of '`mpatrol.h`' to line 34 so that we can replace calls to `malloc()` and `free()` with their mpatrol equivalents[2]. Then, recompile the program and link it with the mpatrol library. This time, running it with even the simplest of non-empty input lines should cause it to abort!

If you look at the '`mpatrol.log`' file produced, you should see something along the lines of the following at the end of the log file.

```
ERROR: free memory corruption at 0x8000706C
        0x8000706C  00555555 55555555 55555555 55555555  .UUUUUUUUUUUUUUU

        0x8000710C  55555555 55555555 55555555 55555555  UUUUUUUUUUUUUUUU
        0x8000711C  55555555 55555555 55555555 55555555  UUUUUUUUUUUUUUUU
        0x8000712C  55555555 55555555 55555555 55555555  UUUUUUUUUUUUUUUU
```

[1] On UNIX systems with dynamic linking it might also be possible to run the program under the mpatrol shell script with its '`-d`' option without having to recompile or relink, but compiling and linking with the mpatrol library is a more generic solution across different platforms.

[2] This is not strictly necessary on UNIX and Windows platforms (and AmigaOS when using `gcc`), but it does give us more debugging information.

```
        0x8000713C  55555555 55555555 55555555 55555555  UUUUUUUUUUUUUUUU
        0x8000714C  55555555 55555555 55555555 55555555  UUUUUUUUUUUUUUUU
        0x8000715C  55555555 55555555 55555555 55555555  UUUUUUUUUUUUUUUU
```

This tells us that something has written a zero byte into free memory at location '0x8000706C'. Unfortunately, the library only caught it at the next call to one of its functions so it had already happened somewhere in between the last call and the current call. Turning on the 'LOGALL' option in the MPATROL_OPTIONS environment variable allows us to see the last successful function call to the mpatrol library.

```
ALLOC: malloc (50, 8192 bytes, 2 bytes) [main|test1.c|54]
        0x80000A30 main (/usr/users/homedir/graeme/test1.c:54)
        0x80000944 _start

returns 0x80009000

ALLOC: malloc (51, 4 bytes, 2 bytes) [strtoupper|test1.c|42]
        0x800009AE strtoupper (/usr/users/homedir/graeme/test1.c:42)
        0x80000A54 main (/usr/users/homedir/graeme/test1.c:57)
        0x80000944 _start

returns 0x80007068
```

Unfortunately, this only tells us that the last successful mpatrol library function call was malloc() called from strtoupper(). If we add the option 'OFLOWSIZE=8' to the MPATROL_OPTIONS environment variable then we get slightly more information about which memory allocation was affected[3].

```
ERROR: allocation 0x80007080 has a corrupted overflow buffer at 0x80007084
        0x80007084  00AAAAAA AAAAAAAA                    ........

    0x80007080 (4 bytes) {malloc:51:0} [strtoupper|test1.c|42]
        0x800009AE strtoupper (/usr/users/homedir/graeme/test1.c:42)
        0x80000A54 main (/usr/users/homedir/graeme/test1.c:57)
        0x80000944 _start
```

Now we can make a better guess about what is happening. Since the start of the upper overflow buffer of allocation 51 has been written to, we can assume that something has written one byte beyond the end of that memory allocation. You can probably see where that is happening now by looking at the code, but let's try to be even more sure that this is what is wrong.

The only foolproof way to do this is to add a software watch point to keep an eye on the address that is being written to. This can normally only be done within a debugger, but on systems that support programmable software watch points, the 'OFLOWWATCH' option can be used to do the same thing. For the sake of generality, we'll use the debugger watch point approach, in this case with gdb. In order for the following example to work correctly you'll need to add the 'ALLOCSTOP=51' option to the MPATROL_OPTIONS environment variable so that we can stop just after the last successful memory allocation.

```
(gdb) break main
```

[3] Note that the start address of the allocation has changed slightly since we added padding around it with the 'OFLOWSIZE' option.

```

```

After loading the program into `gdb`, we need to break at `main()` so that we can run to a point where all of the shared library symbols have been loaded into memory[4]. We can then set another breakpoint at `__mp_trap()` and continue until allocation 51 has been reached.

Because the mpatrol library has not been built with debugging information in this example we can quickly step back to the `strtoupper()` function since `gdb` won't step through functions that have no debugging information. We then set a watch point on address

[4] This is only necessary when the mpatrol library has been built as a shared library.

'0x80007084', which is the address of the memory location that has been causing the problems. After continuing, the debugger stops at line 46, but this is more likely to be line 45 since that is where a zero byte is being written to[5].

So, we have located the problem, which is simply a case of not allocating enough memory to contain the copied string *and* the terminating zero byte. We can also improve the `strtoupper()` function by checking the pointer returned by `malloc()` to see if it is 'NULL', and if so simply exit with an error. You can try running the program with the 'FAILFREQ' option to see how it would originally behave in a low memory situation.

The following listing shows the above modifications that we have made to our program. It can also be found in 'tests/tutorial/test2.c'.

```
23  /*
24   * Reads the standard input file stream, converts all lowercase
25   * characters to uppercase, and displays all non-empty lines to the
26   * standard output file stream.
27   */

30  #include <stdio.h>
31  #include <stdlib.h>
32  #include <string.h>
33  #include <ctype.h>
34  #include "mpatrol.h"

37  char *strtoupper(char *s)
38  {
39      char *t;
40      size_t i, l;

42      l = strlen(s);
43      if ((t = (char *) malloc(l + 1)) == NULL)
44      {
45          fputs("strtoupper: out of memory\n", stderr);
46          exit(EXIT_FAILURE);
47      }
48      for (i = 0; i < l; i++)
49          t[i] = toupper(s[i]);
50      t[i] = '\0';
51      return t;
52  }

55  int main(void)
56  {
57      char *b, *s;
```

[5] This is not necessarily the fault of the debugger or the debugging information generated by the compiler since on most platforms such watchpoints can only be caught after they occur, hence most debuggers show the next statement to be executed rather than the current one.

```
59      b = malloc(BUFSIZ);
60      while (gets(b))
61      {
62          s = strtoupper(b);
63          if (*s != '\0')
64          {
65              puts(s);
66              free(s);
67          }
68      }
69      free(b);
70      return EXIT_SUCCESS;
71  }
```

Leaving aside the obvious problem with `gets()` and the general inefficiency of the algorithm, we could assume that our program works safely now and we can release it to the outside world. However, a user soon reports a problem with our program steadily using more and more memory during its execution when processing very large files.

This is generally attributable to a memory leak and so we can use the '`SHOWUNFREED`' option to try to detect where the memory leak is coming from. Following is some example output from the mpatrol log file when our program is run and is given a relatively small text file as input.

```
unfreed allocations: 6 (109 bytes)
    0x80007000 (104 bytes) {malloc:1:0} [-|-|-]
        0xC008DB4A _IO_fopen
        0xC00183DC __mp_openlogfile
        0xC001A3A4 __mp_init
        0xC001A584 __mp_alloc
        0x80000A98 main
        0x80000980 _start

    0x80007068 (1 byte) {malloc:52:0} [strtoupper|test2.c|43]
        0x800009EE strtoupper
        0x80000ABC main
        0x80000980 _start

    0x8000706A (1 byte) {malloc:54:0} [strtoupper|test2.c|43]
        0x800009EE strtoupper
        0x80000ABC main
        0x80000980 _start

    0x8000706C (1 byte) {malloc:56:0} [strtoupper|test2.c|43]
        0x800009EE strtoupper
        0x80000ABC main
        0x80000980 _start

    0x8000706E (1 byte) {malloc:58:0} [strtoupper|test2.c|43]
        0x800009EE strtoupper
```

```
        0x80000ABC main
        0x80000980 _start

    0x80007070 (1 byte) {malloc:60:0} [strtoupper|test2.c|43]
        0x800009EE strtoupper
        0x80000ABC main
        0x80000980 _start
```

We can discount the first entry since that is obviously coming from when the mpatrol library first initialises itself. However, all of the other entries appear to be coming from line 43 within `strtoupper()` and appear to be only 1 byte in length. At that point in the code, the only possible reason for allocating 1 byte is when the string is empty and so that must mean that we are not freeing memory that contains empty strings. Looking at line 66 we can see that `free()` is only ever called for non-empty strings and therefore if we move the call to `free()` outside the test for an empty string we will fix the memory leak. The file '`tests/tutorial/test3.c`' contains the source for the final program.

Appendix A Functions

The mpatrol library contains implementations of dynamic memory allocation functions for C and C++ suitable for tracing and debugging. The library is intended to be used without requiring any changes to existing user source code except the inclusion of the '`mpatrol.h`' header file, although additional functions are supplied for extra tracing and control. Note that the current version of the mpatrol library is contained in the `MPATROL_VERSION` preprocessor macro.

The following 14 functions are available as replacements for existing C library functions. To use these you must include '`mpatrol.h`' before all other header files, although on UNIX and Windows platforms (and AmigaOS when using `gcc`) they will be used anyway, albeit with slightly less tracing information.

`void *malloc(size_t size)`

Allocates *size* uninitialized bytes from the heap and returns a pointer to the first byte of the allocation. The pointer returned will be suitably aligned for casting to any type and can be used to store data of up to *size* bytes in length. If *size* is '`0`' then the memory allocated will be implicitly rounded up to '`1`' byte. If there is not enough space in the heap then the '`NULL`' pointer will be returned and `errno` will be set to `ENOMEM`. The allocated memory must be deallocated with `free()` or reallocated with `realloc()`.

`void *calloc(size_t nelem, size_t size)`

Allocates *nelem* elements of *size* zero-initialized bytes from the heap and returns a pointer to the first byte of the allocation. The pointer returned will be suitably aligned for casting to any type and can be used to store data of up to `nelem * size` bytes in length. If `nelem * size` is '`0`' then the amount of memory allocated will be implicitly rounded up to '`1`' byte. If there is not enough space in the heap then the '`NULL`' pointer will be returned and `errno` will be set to `ENOMEM`. The allocated memory must be deallocated with `free()` or reallocated with `realloc()`.

`void *memalign(size_t align, size_t size)`

Allocates *size* uninitialized bytes from the heap and returns a pointer to the first byte of the allocation. The pointer returned will be aligned to *align* bytes and can be used to store data of up to *size* bytes in length. If *align* is zero then the default system alignment will be used. If *align* is not a power of two then it will be rounded up to the nearest power of two. If *align* is greater than the system page size then it will be truncated to that value. If *size* is '`0`' then the memory allocated will be implicitly rounded up to '`1`' byte. If there is not enough space in the heap then the '`NULL`' pointer will be returned and `errno` will be set to `ENOMEM`. The allocated memory must be deallocated with `free()` or reallocated with `realloc()`, although the latter will not guarantee the preservation of alignment.

`void *valloc(size_t size)`

Allocates *size* uninitialized bytes from the heap and returns a pointer to the first byte of the allocation. The pointer returned will be aligned to the system

page size and can be used to store data of up to *size* bytes in length. If *size* is '0' then the memory allocated will be implicitly rounded up to '1' byte. If there is not enough space in the heap then the 'NULL' pointer will be returned and errno will be set to ENOMEM. The allocated memory must be deallocated with free() or reallocated with realloc(), although the latter will not guarantee the preservation of alignment.

void *pvalloc(size_t size)
: Allocates *size* uninitialized bytes from the heap and returns a pointer to the first byte of the allocation. The pointer returned will be aligned to the system page size and can be used to store data of up to *size* bytes in length. If *size* is '0' then the memory allocated will be implicitly rounded up to '1' page, otherwise *size* will be implicitly rounded up to a multiple of the system page size. If there is not enough space in the heap then the 'NULL' pointer will be returned and errno will be set to ENOMEM. The allocated memory must be deallocated with free() or reallocated with realloc(), although the latter will not guarantee the preservation of alignment.

char *strdup(const char *str)
: Allocates exactly enough memory from the heap to duplicate *str* (including the terminating nul character) and returns a pointer to the first byte of the allocation after copying *str* to the newly-allocated memory. The pointer returned will have no alignment constraints and can be used to store character data up to the length of *str*. If *str* is 'NULL' then the 'NULL' pointer will be returned. If there is not enough space in the heap then the 'NULL' pointer will be returned and errno will be set to ENOMEM. The allocated memory must be deallocated with free() or reallocated with realloc().

char *strndup(const char *str, size_t size)
: Allocates exactly enough memory from the heap to duplicate *str* (including the terminating nul character) and returns a pointer to the first byte of the allocation after copying *str* to the newly-allocated memory. The pointer returned will have no alignment constraints and can be used to store character data up to the length of *str*. If *str* is 'NULL' then the 'NULL' pointer will be returned. If the length of *str* is greater than *size* then only *size* characters will be allocated and copied, with one additional byte for the nul character. If there is not enough space in the heap then the 'NULL' pointer will be returned and errno will be set to ENOMEM. The allocated memory must be deallocated with free() or reallocated with realloc(). This function is available for backwards compatibility with older C libraries and should not be used in new code.

char *strsave(const char *str)
: Allocates exactly enough memory from the heap to duplicate *str* (including the terminating nul character) and returns a pointer to the first byte of the allocation after copying *str* to the newly-allocated memory. The pointer returned will have no alignment constraints and can be used to store character data up to the length of *str*. If *str* is 'NULL' then the 'NULL' pointer will be returned. If there is not enough space in the heap then the 'NULL' pointer will be returned and errno will be set to ENOMEM. The allocated memory must be deallocated with

`free()` or reallocated with `realloc()`. This function is available for backwards compatibility with older C libraries and should not be used in new code.

`char *strnsave(const char *str, size_t size)`
: Allocates exactly enough memory from the heap to duplicate *str* (including the terminating nul character) and returns a pointer to the first byte of the allocation after copying *str* to the newly-allocated memory. The pointer returned will have no alignment constraints and can be used to store character data up to the length of *str*. If *str* is '`NULL`' then the '`NULL`' pointer will be returned. If the length of *str* is greater than *size* then only *size* characters will be allocated and copied, with one additional byte for the nul character. If there is not enough space in the heap then the '`NULL`' pointer will be returned and `errno` will be set to `ENOMEM`. The allocated memory must be deallocated with `free()` or reallocated with `realloc()`. This function is available for backwards compatibility with older C libraries and should not be used in new code.

`void *realloc(void *ptr, size_t size)`
: Resizes the memory allocation beginning at *ptr* to *size* bytes and returns a pointer to the first byte of the new allocation after copying *ptr* to the newly-allocated memory, which will be truncated if *size* is smaller than the original allocation. The pointer returned will be suitably aligned for casting to any type and can be used to store data of up to *size* bytes in length. If *ptr* is '`NULL`' then the call will be equivalent to `malloc()`. If *size* is '`0`' then the existing memory allocation will be freed and the '`NULL`' pointer will be returned. If *size* is greater than the original allocation then the extra space will be filled with uninitialized bytes. If there is not enough space in the heap then the '`NULL`' pointer will be returned and `errno` will be set to `ENOMEM`. The allocated memory must be deallocated with `free()` and can be reallocated again with `realloc()`.

`void *recalloc(void *ptr, size_t size)`
: Resizes the memory allocation beginning at *ptr* to *size* bytes and returns a pointer to the first byte of the new allocation after copying *ptr* to the newly-allocated memory, which will be truncated if *size* is smaller than the original allocation. The pointer returned will be suitably aligned for casting to any type and can be used to store data of up to *size* bytes in length. If *ptr* is '`NULL`' then the call will be equivalent to `calloc()`. If *size* is '`0`' then the existing memory allocation will be freed and the '`NULL`' pointer will be returned. If *size* is greater than the original allocation then the extra space will be filled with zero-initialized bytes. If there is not enough space in the heap then the '`NULL`' pointer will be returned and `errno` will be set to `ENOMEM`. The allocated memory must be deallocated with `free()` and can be reallocated again with `realloc()`. This function is available for backwards compatibility with older C libraries and `calloc()` and should not be used in new code.

`void *expand(void *ptr, size_t size)`
: Attempts to resize the memory allocation beginning at *ptr* to *size* bytes and either returns *ptr* if there was enough space to resize it, or '`NULL`' if the block could not be resized for a particular reason. If *ptr* is '`NULL`' then the call will be equivalent to `malloc()`. If *size* is '`0`' then the existing memory allocation will be

freed and the 'NULL' pointer will be returned. If *size* is greater than the original allocation then the extra space will be filled with uninitialized bytes and if *size* is less than the original allocation then the memory block will be truncated. If there is not enough space in the heap then the 'NULL' pointer will be returned and errno will be set to ENOMEM. The allocated memory must be deallocated with free() and can be reallocated again with realloc(). This function is available for backwards compatibility with older C libraries and should not be used in new code.

void free(void *ptr)
: Frees the memory allocation beginning at *ptr* so the memory can be reused by another call to allocate memory. If *ptr* is 'NULL' then no memory will be freed. All of the previous contents will be destroyed.

void cfree(void *ptr)
: Frees the memory allocation beginning at *ptr* so the memory can be reused by another call to allocate memory. If *ptr* is 'NULL' then no memory will be freed. All of the previous contents will be destroyed. This function is available for backwards compatibility with older C libraries and calloc() and should not be used in new code.

The following 5 functions are available as replacements for existing C++ library functions, but the replacements in 'mpatrol.h' will only be used if the MP_NOCPLUSPLUS preprocessor macro is not defined. To use these you must include 'mpatrol.h' before all other header files, although on UNIX and Windows platforms (and AmigaOS when using gcc) they will be used anyway, albeit with slightly less tracing information.

void *operator new(size_t size)
: Allocates *size* uninitialized bytes from the heap and returns a pointer to the first byte of the allocation. The pointer returned will be suitably aligned for casting to any type and can be used to store data of up to *size* bytes in length. If *size* is '0' then the memory allocated will be implicitly rounded up to '1' byte. If there is not enough space in the heap then the 'NULL' pointer will be returned and errno will be set to ENOMEM — no exceptions will be thrown. The allocated memory must be deallocated with operator delete.

void *operator new[](size_t size)
: Allocates *size* uninitialized bytes from the heap and returns a pointer to the first byte of the allocation. The pointer returned will be suitably aligned for casting to any type and can be used to store data of up to *size* bytes in length. If *size* is '0' then the memory allocated will be implicitly rounded up to '1' byte. If there is not enough space in the heap then the 'NULL' pointer will be returned and errno will be set to ENOMEM — no exceptions will be thrown. The allocated memory must be deallocated with operator delete[].

void operator delete(void *ptr)
: Frees the memory allocation beginning at *ptr* so the memory can be reused by another call to allocate memory. If *ptr* is 'NULL' then no memory will be freed. All of the previous contents will be destroyed. This function must only be used with memory allocated by operator new.

`void operator delete[](void *ptr)`
: Frees the memory allocation beginning at *ptr* so the memory can be reused by another call to allocate memory. If *ptr* is '`NULL`' then no memory will be freed. All of the previous contents will be destroyed. This function must only be used with memory allocated by `operator new[]`.

`void (*set_new_handler(void (*func)(void)))(void)`
: Installs a low-memory handler specifically for use with `operator new` and `operator new[]` and returns a pointer to the previously installed handler, or the '`NULL`' pointer if no handler had been previously installed. This will be called repeatedly by both functions when they would normally return '`NULL`', and this loop will continue until they manage to allocate the requested space. The default low-memory handler for the C++ operators will terminate the program and write an out of memory message to the log file. Note that this function is equivalent to `__mp_nomemory()` and will replace the handler installed by that function.

The following 9 functions are available as replacements for existing C library memory operation functions. To use these you must include '`mpatrol.h`' before all other header files, although on UNIX and Windows platforms (and AmigaOS when using `gcc`) they will be used anyway, albeit with slightly less tracing information.

`void *memset(void *ptr, int byte, size_t size)`
: Writes *size* bytes of value *byte* to the memory location beginning at *ptr* and returns *ptr*. If *size* is '`0`' then no bytes will be written. If the operation would affect an existing memory allocation in the heap but would straddle that allocation's boundaries then an error message will be generated in the log file and no bytes will be written.

`void bzero(void *ptr, size_t size)`
: Writes *size* zero bytes to the memory location beginning at *ptr*. If *size* is '`0`' then no bytes will be written. If the operation would affect an existing memory allocation in the heap but would straddle that allocation's boundaries then an error message will be generated in the log file and no bytes will be written. This function is available for backwards compatibility with older C libraries and should not be used in new code.

`void *memcpy(void *dest, const void *src, size_t size)`
: Copies *size* bytes from *src* to *dest* and returns *dest*. If *size* is '`0`' or *src* is the same as *dest* then no bytes will be copied. The source and destination ranges should not overlap, otherwise a warning will be written to the log file. If the operation would affect an existing memory allocation in the heap but would straddle that allocation's boundaries then an error message will be generated in the log file and no bytes will be copied.

`void *memmove(void *dest, const void *src, size_t size)`
: Copies *size* bytes from *src* to *dest* and returns *dest*. If *size* is '`0`' or *src* is the same as *dest* then no bytes will be copied. If the operation would affect an existing memory allocation in the heap but would straddle that allocation's

boundaries then an error message will be generated in the log file and no bytes will be copied.

`void bcopy(const void *src, void *dest, size_t size)`
: Copies *size* bytes from *src* to *dest*. If *size* is '`0`' or *src* is the same as *dest* then no bytes will be copied. If the operation would affect an existing memory allocation in the heap but would straddle that allocation's boundaries then an error message will be generated in the log file and no bytes will be copied. This function is available for backwards compatibility with older C libraries and should not be used in new code.

`int memcmp(const void *ptr1, const void *ptr2, size_t size)`
: Compares *size* bytes from *ptr1* and *ptr2* and returns '`0`' if all of the bytes are identical, or returns the byte difference of the first differing bytes. If *size* is '`0`' or *ptr1* is the same as *ptr2* then no bytes will be compared. If the operation would read from an existing memory allocation in the heap but would straddle that allocation's boundaries then an error message will be generated in the log file and no bytes will be compared.

`int bcmp(const void *ptr1, const void *ptr2, size_t size)`
: Compares *size* bytes from *ptr1* and *ptr2* and returns '`0`' if all of the bytes are identical, or returns the byte difference of the first differing bytes. If *size* is '`0`' or *ptr1* is the same as *ptr2* then no bytes will be compared. If the operation would read from an existing memory allocation in the heap but would straddle that allocation's boundaries then an error message will be generated in the log file and no bytes will be compared. This function is available for backwards compatibility with older C libraries and should not be used in new code.

`void *memchr(const void *ptr, int byte, size_t size)`
: Searches up to *size* bytes in *ptr* for the first occurrence of *byte* and returns a pointer to it or '`NULL`' if no such byte occurs. If *size* is '`0`' then no bytes will be searched. If the operation would affect an existing memory allocation in the heap but would straddle that allocation's boundaries then an error message will be generated in the log file and no bytes will be searched.

`void *memmem(const void *ptr1, size_t size1, const void *ptr2, size_t size2)`
: Searches up to *size1* bytes in *ptr1* for the first occurrence of *ptr2* (which is exactly *size2* bytes in length) and returns a pointer to it or '`NULL`' if no such sequence of bytes occur. If *size1* or *size2* is '`0`' then no bytes will be searched. If the operation would affect an existing memory allocation in the heap but would straddle that allocation's boundaries then an error message will be generated in the log file and no bytes will be searched.

The following 7 functions are available as support routines for additional control and tracing in the mpatrol library. To use these you should include the '`mpatrol.h`' header file.

`int __mp_info(const void *ptr, __mp_allocinfo *info)`
: Obtains information about a specific memory allocation by placing statistics about *ptr* in *info*. If *ptr* does not belong to a previously allocated memory allocation then '`0`' will be returned, otherwise '`1`' will be returned and *info* will contain the following information:

Field	*Description*
`block`	Pointer to first byte of allocation.
`size`	Size of allocation in bytes.
`type`	Type of function which allocated memory.
`alloc`	Allocation index.
`realloc`	Number of times reallocated.
`thread`	Thread identifier.
`func`	Function in which allocation took place.
`file`	File in which allocation took place.
`line`	Line number at which allocation took place.
`stack`	Pointer to function call stack.
`freed`	Indicates if allocation has been freed.

`void __mp_memorymap(int stats)`

If *stats* is non-zero then the current statistics of the mpatrol library will be displayed. If the heap contains at least one allocated, freed or free block then a map of the current heap will also be displayed.

`void __mp_summary(void)`

Displays information about the current state of the mpatrol library, including its settings and any relevant statistics.

`void __mp_check(void)`

Forces the library to perform an immediate check of the overflow buffers of every memory allocation and to ensure that nothing has overwritten any free blocks.

`void (*__mp_prologue(void (*func)(const void *, size_t)))(const void *, size_t)`

Installs a prologue function to be called before any memory allocation, reallocation or deallocation function. This function will return a pointer to the previously installed prologue function, or the '`NULL`' pointer if no prologue function had been previously installed. The following arguments will be used to call the prologue function:

Argument 1	*Argument 2*	*Called by*
`-1`	*size*	`malloc()`, etc.
ptr	*size*	`realloc()`, etc.
ptr	`-1`	`free()`, etc.
ptr	`-2`	`strdup()`, etc.

`void (*__mp_epilogue(void (*func)(const void *)))(const void *)`

Installs an epilogue function to be called after any memory allocation, reallocation or deallocation function. This function will return a pointer to the previously installed epilogue function, or the '`NULL`' pointer if no epilogue function had been previously installed. The following arguments will be used to call the epilogue function:

Argument	*Called by*
ptr	`malloc()`, `realloc()`, `strdup()`, etc.
`-1`	`free()`, etc.

`void (*__mp_nomemory(void (*func)(void)))(void)`

Installs a low-memory handler and returns a pointer to the previously installed handler, or the '`NULL`' pointer if no handler had been previously installed. This will be called once by C memory allocation functions, and repeatedly by C++ memory allocation functions, when they would normally return '`NULL`'. Note that this function is equivalent to `set_new_handler()` and will replace the handler installed by that function.

Appendix B Environment

The library can read certain options at run-time from an environment variable called `MPATROL_OPTIONS`. This variable must contain one or more valid option keywords from the list below and must be no longer than 1024 characters in length. If `MPATROL_OPTIONS` is unset or empty then the default settings will be used.

The syntax for options specified within the `MPATROL_OPTIONS` environment variable is '`OPTION`' or '`OPTION=VALUE`', where '`OPTION`' is a keyword from the list below and '`VALUE`' is the setting for that option. If '`VALUE`' is numeric then it may be specified using binary, octal, decimal or hexadecimal notation, with binary notation beginning with either '`0b`' or '`0B`'. If '`VALUE`' is a character string containing spaces then it may be quoted using double quotes. No whitespace may appear between the '`=`' sign, but whitespace must appear between different options. Note that option keywords can be given in lowercase as well as uppercase, or a mixture of both.

'`ALLOCBYTE`'=<*unsigned-integer*>
: Specifies an 8-bit byte pattern with which to prefill newly-allocated memory. This can be used to detect the use of memory which has not been initialised after allocation. Note that this setting will not affect memory allocated with `calloc()` or `recalloc()` as these functions always prefill allocated memory with an 8-bit byte pattern of zero. Default value: '`ALLOCBYTE=0xFF`'.

'`ALLOCSTOP`'=<*unsigned-integer*>
: Specifies an allocation index at which to stop the program when it is being allocated. When the number of memory allocations reaches this number the program will be halted, and its state may be examined at that point by using a suitable debugger. Note that this setting will be ignored if its value is zero. Default value: '`ALLOCSTOP=0`'.

'`CHECK`'=<*unsigned-range*>
: Specifies a range of allocation indices at which to check the integrity of free memory and overflow buffers. The range must be specified as no more than two unsigned integers separated by a dash. If numbers on either the left side or the right side of the dash are omitted then they will be assumed to be '`0`' and *infinity* respectively. A value of '`0`' on its own indicates that no such checking will ever be performed. This option can be used to speed up the execution speed of the library at the expense of checking. Default value: '`CHECK=-`'.

'`CHECKALL`'
: Equivalent to the '`CHECKALLOCS`', '`CHECKREALLOCS`' and '`CHECKFREES`' options specified together.

'`CHECKALLOCS`'
: Checks that no attempt is made to allocate a block of memory of size zero. A warning will be issued for every such case.

'`CHECKFREES`'
: Checks that no attempt is made to deallocate a '`NULL`' pointer. A warning will be issued for every such case.

'CHECKREALLOCS'
: Checks that no attempt is made to reallocate a 'NULL' pointer or resize an existing block of memory to size zero. Warnings will be issued for every such case.

'DEFALIGN'=<*unsigned-integer*>
: Specifies the default alignment for general-purpose memory allocations, which must be a power of two (and will be rounded up to the nearest power of two if it is not). The default alignment for a particular system is calculated at run-time.

'FAILFREQ'=<*unsigned-integer*>
: Specifies the frequency at which all memory allocations will randomly fail. For example, a value of '10' will mean that roughly 1 in 10 memory allocations will fail, but a value of '0' will disable all random failures. This option can be useful for stress-testing an application. Default value: 'FAILFREQ=0'.

'FAILSEED'=<*unsigned-integer*>
: Specifies the random number seed which will be used when determining which memory allocations will randomly fail. A value of '0' will instruct the library to pick a random seed every time it is run. Any other value will mean that the random failures will be the same every time the program is run, but only as long as the seed stays the same. Default value: 'FAILSEED=0'.

'FREEBYTE'=<*unsigned-integer*>
: Specifies an 8-bit byte pattern with which to prefill newly-freed memory. This can be used to detect the use of memory which has just been freed. It is also used internally to ensure that freed memory has not been overwritten. Note that the freed memory may be reused the next time a block of memory is allocated and so once memory has been freed its contents are not guaranteed to remain the same as the specified byte pattern. Default value: 'FREEBYTE=0x55'.

'FREESTOP'=<*unsigned-integer*>
: Specifies an allocation index at which to stop the program when it is being freed. When the memory allocation with the specified allocation index is to be freed the program will be halted, and its state may be examined at that point using a suitable debugger. Note that this setting will be ignored if its value is zero. Default value: 'FREESTOP=0'.

'HELP'
: Displays a quick-reference option summary to the `stderr` file stream.

'LIMIT'=<*unsigned-integer*>
: Specifies the limit in bytes at which all memory allocations should fail if the total allocated memory should increase beyond this. This can be used to stress-test software to see how it behaves in low memory conditions. The internal memory used by the library itself will not be counted as part of the total heap size, but on some systems there may be a small amount of memory required to initialise the library itself. Note that this setting will be ignored if its value is zero. Default value: 'LIMIT=0'.

'LOGALL'
: Equivalent to the 'LOGALLOCS', 'LOGREALLOCS', 'LOGFREES' and 'LOGMEMORY' options specified together.

'LOGALLOCS'
: Specifies that all memory allocations are to be logged and sent to the log file. Note that any memory allocations made internally by the library will not be logged.

'LOGFILE'=<*string*>
: Specifies an alternative file in which to place all diagnostics from the mpatrol library. A filename of '`stderr`' will send all diagnostics to the `stderr` file stream and a filename of '`stdout`' will do the equivalent with the `stdout` file stream. Note that if a problem occurs while opening the log file or if any diagnostics require to be displayed before the log file has had a chance to be opened then they will be sent to the `stderr` file stream. Default value: '`LOGFILE=mpatrol.log`'.

'LOGFREES'
: Specifies that all memory deallocations are to be logged and sent to the log file. Note that any memory deallocations made internally by the library will not be logged.

'LOGMEMORY'
: Specifies that all memory operations are to be logged and sent to the log file. These operations will be made by calls to functions such as `memset()` and `memcpy()`. Note that any memory operations made internally by the library will not be logged.

'LOGREALLOCS'
: Specifies that all memory reallocations are to be logged and sent to the log file. Note that any memory reallocations made internally by the library will not be logged.

'NOFREE'
: Specifies that the mpatrol library should keep all reallocated and freed memory allocations. Such freed memory allocations will then be flagged as freed and can be used by the library to provide better diagnostics. However, as no system memory will ever be reused by the mpatrol library, this option can quickly lead to a shortage of available system memory for a process. Note that this option will always force a memory reallocation to return a pointer to newly-allocated memory, but the `expand()` function will never be affected by this option.

'NOPROTECT'
: Specifies that the mpatrol library's internal data structures should not be made read-only after every memory allocation reallocation or deallocation. This may significantly speed up execution but this will be at the expense of less safety if the program accidentally overwrites some of the library's internal data structures. Note that this option has no effect on systems that do not support memory protection.

'OFLOWBYTE'=<*unsigned-integer*>
: Specifies an 8-bit byte pattern with which to fill the overflow buffers of all memory allocations. This is used internally to ensure that nothing has been written beyond the beginning or the end of a block of allocated memory. Note that this setting will only have an effect if the '`OFLOWSIZE`' option is in use. Default value: '`OFLOWBYTE=0xAA`'.

'OFLOWSIZE'=<*unsigned-integer*>
: Specifies the size in bytes to use for all overflow buffers, which must be a power of two (and will be rounded up to the nearest power of two if it is not). This is used internally to ensure that nothing has been written beyond the beginning or the end of a block of allocated memory. Note that this setting specifies the size for only one of the overflow buffers given to each memory allocation; the other overflow buffer will have an identical size. No overflow buffers will be used if this setting is zero. Default value: 'OFLOWSIZE=0'.

'OFLOWWATCH'
: Specifies that watch point areas should be used for overflow buffers rather than filling with the overflow byte. This can significantly reduce the speed of program execution. Note that this option has no effect on systems that do not support watch point areas.

'PAGEALLOC'=<'LOWER'|'UPPER'>
: Specifies that each individual memory allocation should occupy at least one page of virtual memory and should be placed at the lowest or highest point within these pages. This allows the library to place an overflow buffer of one page on either side of every memory allocation and write-protect these pages as well as all free and freed memory. Note that this option has no effect on systems that do not support memory protection, and is disabled by default on other systems as it can slow down the speed of program execution.

'PRESERVE'
: Specifies that any reallocated or freed memory allocations should preserve their original contents. This option must be used with the 'NOFREE' option and has no effect otherwise.

'PROGFILE'=<*string*>
: Specifies an alternative filename with which to locate the executable file containing the program's symbols. On most systems, the library will automatically be able to determine this filename, but on a few systems this option may have to be used before any or all symbols can be read.

'REALLOCSTOP'=<*unsigned-integer*>
: Specifies a reallocation index at which to stop the program when a memory allocation is being reallocated. If the 'ALLOCSTOP' option is non-zero then the program will be halted when the allocation matching that allocation index is reallocated the specified number of times. Otherwise the program will be halted the first time any allocation is reallocated the specified number of times. Note that this setting will be ignored if its value is zero. Default value: 'REALLOCSTOP=0'.

'SAFESIGNALS'
: Instructs the library to save and replace certain signal handlers during the execution of library code and to restore them afterwards. This was the default behaviour in version 1.0 of the mpatrol library and was changed since some memory-intensive programs became very hard to interrupt using the keyboard, thus giving the impression that the program or system had hung.

'SHOWALL' Equivalent to the 'SHOWFREED', 'SHOWUNFREED', 'SHOWMAP' and 'SHOWSYMBOLS' options specified together.

'SHOWFREED'
Specifies that a summary of all of the freed memory allocations should be displayed at the end of program execution. This option must be used in conjunction with the 'NOFREE' option and this step will not be performed if an abnormal termination occurs or if there were no freed allocations.

'SHOWMAP' Specifies that a memory map of the entire heap should be displayed at the end of program execution. This step will not be performed if an abnormal termination occurs or if the heap is empty.

'SHOWSYMBOLS'
Specifies that a summary of all of the function symbols read from the program's executable file should be displayed at the end of program execution. This step will not be performed if an abnormal termination occurs or if no symbols could be read from the executable file.

'SHOWUNFREED'
Specifies that a summary of all of the unfreed memory allocations should be displayed at the end of program execution. This step will not be performed if an abnormal termination occurs or if there are no unfreed allocations.

'UNFREEDABORT'=<*unsigned-integer*>
Specifies the minimum number of unfreed allocations at which to abort the program just before program termination. A summary of all the allocations will be displayed on the standard error file stream before aborting. This option may be handy for use in batch tests as it can force tests to fail if they do not free up a minimum number of memory allocations. Note that this setting will be ignored if its value is zero. Default value: 'UNFREEDABORT=0'.

'USEDEBUG'
Specifies that any debugging information in the executable file should be used to obtain additional source-level information. This option will only have an effect if the executable file contains a compiler-generated line number table and will be ignored if the mpatrol library was built to support an object file access library that cannot read line tables from object files. Note that this option will slow down program execution, use up more system memory and may leave unaccounted unfreed memory allocations at program termination.

'USEMMAP' Specifies that the library should use `mmap()` instead of `sbrk()` to allocate system memory on UNIX platforms. This option should be used if there are problems when using the mpatrol library in combination with another malloc library which uses `sbrk()` to allocate its memory. It is ignored on systems that do not support the `mmap()` system call.

Appendix C Options

On UNIX platforms, a shell script called `mpatrol` is provided to run commands that have been linked with the mpatrol library.

```
mpatrol [options] <command> [arguments]
```

The `mpatrol` command is used to set various mpatrol library *options* when running *command* with its *arguments*. In most cases, *command* must have been linked with the mpatrol library, unless the '`-d`' option is used in which case *command* need only have been dynamically linked.

All mpatrol library diagnostics are sent to the file '`mpatrol.%n.log`' in the current directory by default (where '`%n`' is the current process id) but this can be changed using the '`-l`' option. Any existing `MPATROL_OPTIONS` environment variable settings which are not overridden by *options* will be passed through unchanged to the mpatrol library.

All of the following options (except '`-d`') correspond to their listed mpatrol library option (see Appendix B [Environment], page 79).

'`-A`' <*unsigned-integer*>
: ['`ALLOCSTOP`'] Specifies an allocation index at which to stop the program when it is being allocated.

'`-a`' <*unsigned-integer*>
: ['`ALLOCBYTE`'] Specifies an 8-bit byte pattern with which to prefill newly-allocated memory.

'`-C`' <*unsigned-range*>
: ['`CHECK`'] Specifies a range of allocation indices at which to check the integrity of free memory and overflow buffers.

'`-c`'
: ['`CHECKALL`'] Specifies that all arguments to functions which allocate, reallocate and deallocate memory have rigorous checks performed on them.

'`-D`' <*unsigned-integer*>
: ['`DEFALIGN`'] Specifies the default alignment for general-purpose memory allocations, which must be a power of two.

'`-d`'
: Specifies that the `LD_PRELOAD` environment variable should be set so that even programs that were not compiled with the mpatrol library can be traced, but only if they were dynamically linked. This option will only work if the dynamic linker recognises the `LD_PRELOAD` environment variable.

'`-e`' <*string*>
: ['`PROGFILE`'] Specifies an alternative filename with which to locate the executable file containing the program's symbols.

'`-F`' <*unsigned-integer*>
: ['`FREESTOP`'] Specifies an allocation index at which to stop the program when it is being freed.

'`-f`' <*unsigned-integer*>
: ['`FREEBYTE`'] Specifies an 8-bit byte pattern with which to prefill newly-freed memory.

‘`-G`’ [‘`SAFESIGNALS`’] Instructs the library to save and replace certain signal handlers during the execution of library code and to restore them afterwards.

‘`-g`’ [‘`USEDEBUG`’] Specifies that any debugging information in the executable file should be used to obtain additional source-level information.

‘`-L`’ <*unsigned-integer*>
[‘`LIMIT`’] Specifies the limit in bytes at which all memory allocations should fail if the total allocated memory should increase beyond this.

‘`-l`’ <*string*>
[‘`LOGFILE`’] Specifies an alternative file in which to place all diagnostics from the mpatrol library.

‘`-m`’ [‘`USEMMAP`’] Specifies that the library should use `mmap()` instead of `sbrk()` to allocate system memory.

‘`-N`’ [‘`NOPROTECT`’] Specifies that the mpatrol library's internal data structures should not be made read-only after every memory allocation, reallocation or deallocation.

‘`-n`’ [‘`NOFREE`’] Specifies that the mpatrol library should keep all reallocated and freed memory allocations.

‘`-O`’ <*unsigned-integer*>
[‘`OFLOWSIZE`’] Specifies the size in bytes to use for all overflow buffers, which must be a power of two.

‘`-o`’ <*unsigned-integer*>
[‘`OFLOWBYTE`’] Specifies an 8-bit byte pattern with which to fill the overflow buffers of all memory allocations.

‘`-P`’ [‘`PAGEALLOC=UPPER`’] Specifies that each individual memory allocation should occupy at least one page of virtual memory and should be placed at the highest point within these pages.

‘`-p`’ [‘`PAGEALLOC=LOWER`’] Specifies that each individual memory allocation should occupy at least one page of virtual memory and should be placed at the lowest point within these pages.

‘`-R`’ <*unsigned-integer*>
[‘`REALLOCSTOP`’] Specifies an allocation index at which to stop the program when a memory allocation is being reallocated.

‘`-S`’ [‘`SHOWMAP`’ & ‘`SHOWSYMBOLS`’] Specifies that a memory map of the entire heap and a summary of all of the function symbols read from the program's executable file should be displayed at the end of program execution.

‘`-s`’ [‘`SHOWFREED`’ & ‘`SHOWUNFREED`’] Specifies that a summary of all of the freed and unfreed memory allocations should be displayed at the end of program execution.

‘`-U`’ <*unsigned-integer*>
[‘`UNFREEDABORT`’] Specifies the minimum number of unfreed allocations at which to abort the program just before program termination.

‘`-v`’ [‘`PRESERVE`’] Specifies that any reallocated or freed memory allocations should preserve their original contents.

‘`-w`’ [‘`OFLOWWATCH`’] Specifies that watch point areas should be used for overflow buffers rather than filling with the overflow byte.

‘`-Z`’ <*unsigned-integer*>
[‘`FAILSEED`’] Specifies the random number seed which will be used when determining which memory allocations will randomly fail.

‘`-z`’ <*unsigned-integer*>
[‘`FAILFREQ`’] Specifies the frequency at which all memory allocations will randomly fail.

Appendix D Library performance

The following times were obtained on a Sun Ultra 5 with an UltraSPARC IIi processor running at 333MHz and running Solaris 7. The test performed was the one in '`tests/pass/test1.c`' and all tests were run on a lightly loaded system, but were run several times to obtain an average result. Obviously, these times can only be an approximation, but should serve to illustrate the effects on performance that each option can have. All times are given in seconds, and the second time on each line was obtained with the same options plus the '`NOPROTECT`' option. Running with the '`CHECK=0`' option would speed things up dramatically, albeit at the expense of less error checking.

Running with basic options:

no options	0.618	0.258
'`OFLOWSIZE=2`'	0.645	0.296
'`OFLOWSIZE=8`'	0.686	0.327
'`PAGEALLOC=LOWER`'	7.785	7.372
'`PAGEALLOC=UPPER`'	7.821	7.469

Running when all freed memory allocations are kept:

'`NOFREE`'	0.943	0.506
'`NOFREE OFLOWSIZE=2`'	1.026	0.579
'`NOFREE OFLOWSIZE=8`'	1.091	0.645
'`NOFREE PAGEALLOC=LOWER`'	8.013	7.598
'`NOFREE PAGEALLOC=UPPER`'	8.026	7.616

Running when all freed memory allocations are kept and their contents are preserved:

'`NOFREE PRESERVE`'	0.719	0.292
'`NOFREE PRESERVE OFLOWSIZE=2`'	0.792	0.367
'`NOFREE PRESERVE OFLOWSIZE=8`'	0.850	0.419
'`NOFREE PRESERVE PAGEALLOC=LOWER`'	8.043	7.616
'`NOFREE PRESERVE PAGEALLOC=UPPER`'	8.052	7.631

Running using watch points to check the overflow buffers:

'`OFLOWSIZE=2 OFLOWWATCH`'	Interrupted after half an hour as it still hadn't finished.

Running using the Solaris 7 malloc libraries:

Solaris 7 malloc(3c) library	0.033
Solaris 7 malloc(3x) library	0.036
Solaris 7 bsdmalloc(3x) library	0.028
Solaris 7 mapmalloc(3x) library	0.033
Solaris 7 watchmalloc(3x) library	40.845

Appendix E Supported systems

Following is a list of systems on which the mpatrol library has been built and tested. The system details include the operating system and version, the processor type, the object file format and the C compiler used to compile the library and tests. The details following each system list any features of the library that are not (or cannot be) supported on that system.

- DG/UX 4.11, Intel Pentium Pro, ELF32, `gcc`
  - The thread-safe version of the library does not work.
  - The '`OFLOWWATCH`' option has no effect.
  - The '`USEDEBUG`' option has no effect.
  - The '`-d`' option to the `mpatrol` shell script has no effect.
- DG/UX 4.11, Motorola 88100, ELF32, `gcc`
  - The thread-safe version of the library does not work.
  - The '`OFLOWWATCH`' option has no effect.
  - The '`USEDEBUG`' option has no effect.
  - Cannot automatically determine the program filename.
  - Call stack traversal only works with unoptimised code.
  - The '`-d`' option to the `mpatrol` shell script has no effect.
- DYNIX/ptx 4.5, Intel Pentium Pro, ELF32, `cc`
  - The thread-safe version of the library does not work.
  - The '`OFLOWWATCH`' option has no effect.
  - The '`USEDEBUG`' option has no effect.
  - The '`-d`' option to the `mpatrol` shell script has no effect.
- HP/UX 10.20, HP PA/RISC 9000, BFD, `gcc`
  - The thread-safe version of the library does not work.
  - The '`OFLOWWATCH`' option has no effect.
  - The '`USEMMAP`' option has no effect.
  - Cannot automatically determine the program filename.
  - No support for call stack traversal.
  - The '`-d`' option to the `mpatrol` shell script has no effect.
- RedHat Linux 6.0, Intel Pentium III, BFD, `gcc`
  - The thread-safe version of the library does not work.
  - The '`OFLOWWATCH`' option has no effect.
  - The address of an illegal memory access cannot be determined.
  - The '`-d`' option to the `mpatrol` shell script does not work properly.
- RedHat Linux 5.1, Motorola 68040, BFD, `gcc`
  - The thread-safe version of the library does not work.

  - The '`OFLOWWATCH`' option has no effect.
  - The address of an illegal memory access cannot be determined.
  - The '`-d`' option to the `mpatrol` shell script does not work properly.
- RedHat Linux 5.1, Motorola 68040, ELF32, `gcc`
  - The thread-safe version of the library does not work.
  - The '`OFLOWWATCH`' option has no effect.
  - The '`USEDEBUG`' option has no effect.
  - The address of an illegal memory access cannot be determined.
  - The '`-d`' option to the `mpatrol` shell script does not work properly.
- LynxOS 3.0.0, PowerPC, BFD, `gcc`
  - The thread-safe version of the library does not work.
  - The '`OFLOWWATCH`' option has no effect.
  - The '`USEMMAP`' option has no effect.
  - Cannot automatically determine the program filename.
  - No support for call stack traversal.
  - The address of an illegal memory access cannot be determined.
  - The '`-d`' option to the `mpatrol` shell script has no effect.
- Solaris 2.6, Intel Pentium Pro, BFD, `gcc`
  - The thread-safe version of the library does not work.
- Solaris 2.6, Intel Pentium Pro, ELF32, `gcc`
  - The thread-safe version of the library does not work.
  - The '`USEDEBUG`' option has no effect.
- Solaris 7, SPARC V9, BFD, `gcc`
  - The thread-safe version of the library does not work.
- Solaris 7, SPARC V9, ELF32, `gcc`
  - The thread-safe version of the library does not work.
  - The '`USEDEBUG`' option has no effect.
- AmigaOS 3.1, Motorola 68040, BFD, `gcc`
  - No memory protection so the '`PAGEALLOC`' option has no effect.
  - The '`OFLOWWATCH`' option has no effect.
  - The '`USEDEBUG`' option has no effect.
  - The '`USEMMAP`' option has no effect.
  - Limited support for call stack traversal.
  - Limited support for reading symbols.
  - No detection of illegal memory accesses.
- AmigaOS 3.1, Motorola 68040, n/a, SAS/C
  - No automatic override of `malloc()`, etc., without inclusion of '`mpatrol.h`'.

  - No memory protection so the '`PAGEALLOC`' option has no effect.
  - The '`OFLOWWATCH`' option has no effect.
  - The '`USEDEBUG`' option has no effect.
  - The '`USEMMAP`' option has no effect.
  - No support for call stack traversal.
  - No support for reading symbols.
  - No detection of illegal memory accesses.
- Microsoft Windows NT 4.0, Intel Pentium III, n/a, Microsoft Visual C/C++
  - The '`OFLOWWATCH`' option has no effect.
  - The '`USEDEBUG`' option has no effect.
  - The '`USEMMAP`' option has no effect.
  - No support for reading symbols.
  - The address of an illegal memory access cannot be determined.

E.1 Adding a new operating system

- Add a new `TARGET` and/or `SYSTEM` definition in '`target.h`'. The `TARGET` macro is for fundamentally different operating systems, whereas the `SYSTEM` macro is for differentiating variations of a particular operating system.
- Make any necessary modifications to '`config.h`'.
- Add any support for memory allocation in '`memory.c`'.
- Add any support for stack traversal in '`stack.c`'.
- Add any support for signals in '`signals.c`'.
- Add any support for threads in '`mutex.c`'.
- Add a new version and date format (or use an existing one) in '`version.c`'.
- Decide if the `malloc()` replacements should be used from '`mpatrol.c`'.
- Add a new subdirectory in the '`build`' directory that contains a '`Makefile`' and any other files that are required to build the library on the new operating system.

E.2 Adding a new processor architecture

- Add a new `ARCH` definition in '`target.h`'.
- Make any necessary modifications to '`config.h`'.
- Add any support for memory allocation in '`memory.c`'.
- Add any support for stack traversal in '`stack.c`'.

E.3 Adding a new object file format

- Add a new `FORMAT` definition in '`target.h`'.
- Make any necessary modifications to '`config.h`'.
- Add any support for stack traversal in '`stack.c`'.
- Add any support for symbol reading in '`symbol.c`'.

Appendix F Notes

This section contains information about known bugs and limitations in the mpatrol library as well as listing potential future enhancements.

Bugs should be reported to mpatrol@cbmamiga.demon.co.uk along with the details of the operating system, processor architecture and object file format that the mpatrol library is being used with — and don't forget to include the version of the mpatrol library you are using! Keep in mind that I only have access to an Amiga running RedHat Linux/m68k 5.1 and AmigaOS 3.1, so I will be most likely unable to reproduce most of the system-specific bugs. A bug report that comes with an associated fix will be most welcome.

Enhancement requests and source code containing enhancements should also be sent to mpatrol@cbmamiga.demon.co.uk or the mpatrol discussion group at http://www.egroups.com/group/mpatrol/. If you are planning to implement an enhancement, let me know first in case I am (or someone else is) working towards the same goal — that way, work won't be wasted. If you wish to send me source code changes please send the changes as context diffs or in an e-mail attachment as a compressed tar archive.

F.1 Notes for all platforms

- C++ support is still fairly limited, and will possibly only work for older C++ code due to the way the operators are overridden (i.e. there are no exceptions versions of the functions). There are also likely to be potential problems with the macros which redefine `malloc()` and `operator new`, etc., since there may be member functions in code that will mistakenly be redefined if their names match the macro definitions, and also means that calls to placement `new` will not work at all. Also, explicit references to `operator new` rather than `new` are likely to result in compilation errors, and the way that source level information is obtained for `operator delete` means that the resulting code will not be thread-safe.
- Need to add support for 64-bit processors. This shouldn't be too hard, but I haven't got access to a 64-bit environment to test it, so I haven't bothered yet.
- The thread-safe code in the library doesn't yet work properly, probably because of the recursion flag which is incremented or decremented before the mutex is locked. Hence, the threads test ('`tests/pass/test5.c`') doesn't work yet.
- Need to make the library re-entrant. This could be achieved by moving the static variables in '`memory.c`', '`mutex.c`', '`diag.c`', '`option.c`' and '`sbrk.c`' into the `infohead` structure and then having an array of `infohead` structures from which to allocate new memory headers when a new one is required. This is only necessary for Amiga shared libraries and Netware NLMs since UNIX and Windows platforms allocate a new copy of the data section in a shared library or DLL when it is opened by a new process.
- The current implementation of call stack traversal is limited and will only likely work for unoptimised code. A much better solution would be write the implementation at a lower level in assembly, but this is much less portable. Perhaps there is a library which can be used to perform this across many operating systems and processor architectures, or maybe someone would like to write one? I can think of many applications that would benefit from such a library besides this one.

- An alternative implementation for call stack traversal uses the functions `__builtin_frame_address()` and `__builtin_return_address()` that are available when the library is compiled with `gcc`. However, they can only traverse a number of stack frames at compile-time, not run-time so there is a maximum number of stack frames that can be traversed at any one time. The implementation depends on both of these builtin functions returning '`NULL`' when the top of stack is reached. If this is not the case then this method cannot be used.
- An option should be added to suppress stack traversal, and therefore symbol reading, in case of problems where the library crashes during reading a call stack.
- In object file formats that support nested symbols (such as ELF), the current implementation will tend to show some shortcomings. This is because there is currently no nesting count in the function that deals with symbol name lookup, so the wrong symbol name may be displayed in diagnostics.
- In object file formats that don't store the sizes of symbols (such as basic COFF, or when using the GNU BFD library), the current implementation will simply assume that the current symbol terminates at the beginning of the next symbol in the virtual address space.
- Perhaps debugging information could be better utilised when the library is reading the symbol table from an executable file. This could be used to add line number information to calls that were not made via '`mpatrol.h`', but this would require cacheing any filenames since they may disappear due to the object file access library freeing them after use.
- Possibly add ability to interface with various debuggers, including `gdb`, which could be used to provide reliable stack traces and symbolic information as well as complete debugging information if available.
- Perhaps add a memory allocation profiling feature (something similar to mprof), which could be used to determine where most of the memory allocations occur, or if bottlenecks could be removed from the code. This could take the form of the library writing out an additional file which could be analysed by an external program, and could take advantage of the stack tracebacks and symbol tables in the mpatrol library.
- Improve use of watch points by allowing an option which will only install write watch points instead of both read and write watch points. Not only will this speed up the use of watch points, but will also cause less problems with reading from misaligned memory allocations.
- Add a '`SHOWFREE`' option to display a list of all free memory blocks at program termination for debugging purposes to view memory fragmentation. If that option is added then perhaps '`SHOWALL`' should only be equivalent to '`SHOWFREE`', '`SHOWFREED`' and '`SHOWUNFREED`', and '`SHOWMAP`' and '`SHOWSYMBOLS`' should be explicitly given.
- Add an option, similar to '`NOFREE`', that would prevent a freed memory allocation from being used until a certain number of memory allocations later. This would be far less of a resource-hogger than the '`NOFREE`' option and might catch just as many errors.
- Add versions of `mallopt()`, `mallinfo()`, `memorymap()`, `mallocctl()`, `mallocblksize()` and `msize()` which are provided in many other malloc libraries. These won't necessarily behave in exactly the same way as existing implementations, but at least there won't be link errors when compiling source code which uses them.

- Perhaps add debugging/tracing versions of the string manipulation functions, such as `strlen()` and `strcmp()` in much the same way as was done for the memory operation functions. The only problem with this would be locale support, but perhaps it might be easier just to assume the C locale to begin with. Also need to add replacement version of `memccpy()`.
- Add another library which can be linked in instead of mpatrol and replaces all calls to `__mp_alloc()`, etc., with the original calls to `malloc()` and related functions. This would be very useful for quickly removing all mpatrol functionality for perhaps even a release build, and might be useful for implementing functions such as `memalign()` which don't exist on many systems.
- Script files similar to the `mpatrol` shell script provided for UNIX platforms could be added for the other operating systems that the mpatrol library is available on. Perhaps this could even be extended to a common executable command that is written in C.
- Perhaps use GNU autoconf to automatically work out values for '`config.h`' on the platform it is being built on, and also use automake, libtool and install when building and installing files.

F.2 Notes for UNIX platforms

- Need to add watch point area support for non-Solaris operating systems. This may be a case of preventing all heap memory from being accessed and providing a signal handler that is called when a read from or write to such memory triggers a signal. The handler could then determine if the address is in a watch point, and if it is not it could unprotect the memory and return.
- Need to improve watch point facility in order to speed it up by an order of magnitudes. This will most likely involve removing all watch points when entering the library and replacing them when returning to user code.
- Need to add advanced signal information for operating systems that do not support the `siginfo()` system call. This information is used by the signal handler that handles the `SIGSEGV` signal in order to provide useful information about where an illegal memory access occurred. However, there is currently a problem in that the call stack displayed from within that handler is not necessarily accurate with respect to the function at the top of the stack. Also, signal handlers shouldn't technically call I/O functions in case of additional signals being caught so this may need to be improved.
- Need to add a portable way of initialising the thread-safe version of the library when it is compiled by a C compiler. There is already a solution to this problem when it is compiled by a C++ compiler.
- Need to add support for call stack traversal for at least the Alpha, MIPS, PA/RISC and PowerPC processor architectures. The current implementation of call stack traversal for the Motorola 88xx0 family is also a bit flaky and so should only be used when the library and program are built unoptimised.
- Need to add support for obtaining the program name from the stack for at least the Alpha, Motorola 88xx0, MIPS, PA/RISC and PowerPC processor architectures. Also need to add support for reading the program symbols from a suitable file in '`/proc`' for other operating systems that support it. If there is no support for either of these

methods then the '`PROGFILE`' option can currently be used to specify the program name at run-time.

- The library cannot currently read any symbols from shared objects that have been read via `dlopen()`.
- There is a problem on later Linux releases where the `_DYNAMIC` symbol is defined in '`elf.h`', thus resulting in a conflicting definition when compiling '`symbol.c`'.
- The '`-d`' option to the `mpatrol` shell script does not always work on systems whose dynamic linkers support the `LD_PRELOAD` environment variable. This needs to be looked into in order to find out the cause.

F.3 Notes for Amiga platforms

- Perhaps add support for building mpatrol as an Amiga shared library. I attempted to do this in a previous release of mpatrol, but it would have involved too many source changes to get working fully. Perhaps it's not even worth implementing as the archive library works fine.
- Need to add proper support for call stack traversal for both the Motorola 680x0 and PowerPC processor architectures. When `gcc` is being used then up to two stack frames can be traversed, but this should really be extended without requiring `MP_BUILTINSTACK_SUPPORT`. When SAS/C is being used then there is no support for call stack traversal.
- Need to add proper support for reading symbols from Amiga executable files. When `gcc` is being used then the BFD library routines will be called to determine the symbols from the executable file, but this will only work for objects compiled with `gcc`. When SAS/C is being used then there is no support for reading symbols from executable files. Also need to add support for reading symbols from any shared libraries that are required by the program.
- Possibly make use of other software such as Enforcer, Mungwall or MuLib in order to provide some form of memory protection. The features of SegTracker could also be put to good use so that the file and hunk location of entries on the call stack could be determined.
- When using SAS/C it is currently not possible to override the definition of `malloc()`, etc., without including the '`mpatrol.h`' header file first. This is because the compiler startup code and libraries call `malloc()` before everything is set up, and so the library cannot properly initialise itself if the `malloc()` that the startup code finds is the `malloc()` in the mpatrol library. This restriction does not exist when using `gcc`.

F.4 Notes for Windows platforms

- Need to add watch point area support, possibly by using guard pages as a basis for an implementation.
- Need to add support for reading symbols from Windows executable files. Also need to add support for reading symbols from any DLLs that are required by the program. This may be possible in a limited fashion by using the GNU BFD library, but may only work with code compiled with `gcc`.

F.5 Notes for Netware platforms

- The library has not yet been built (let alone tested) on Netware platforms. The names of the system functions that the library calls for Netware were obtained by looking at Novell's developer documentation, so they may not even compile correctly without modification.
- Need to add support for building the mpatrol library as an NLM. This is not currently a high priority requirement as the archive library should suffice for most purposes.
- Need to add way to determine when the base of the stack has been reached during call stack traversal, since on Netware every application is really a thread running under one large process.
- Need to add support for reading symbols from Netware load modules. Also need to add support for reading symbols from any NLMs that are required by the program. This may be possible in a limited fashion by using the GNU BFD library, but may only work with code compiled with `gcc`.
- Need to investigate if it is safe (or even possible) to override the definitions of `malloc()`, etc., without including the '`mpatrol.h`' header file first. Currently, non-macro definitions for these functions have been disabled in the Netware version of the library in case they affect other NLMs that are currently running.

Appendix G Related software

A list of software which helps in debugging dynamic memory allocation problems is given below[1]. They all provide some of the features that mpatrol contains and you may wish to use one of them to solve your problem if you have trouble using mpatrol. I have only ever used Dbmalloc and Electric Fence, so I can't vouch for any of the others, although if you have any recommendations feel free to let me know so I can add them to this list. In particular, there seems to be a shortage of such programs for Netware platforms.

- APurify

  Author Samuel Devulder (Samuel.Devulder@info.unicaen.fr)

  License Free Software

  Platforms AmigaOS

  Location http://wuarchive.wustl.edu/~aminet/dirs/dev_debug.html

  Overview Instruments an assembler source file to insert code that checks all memory accesses.

- BoundsChecker

  Author NuMega Corporation (info@numega.com)

  License Commercial Software

  Platforms MS-DOS, Windows

  Location http://www.numega.com/

  Overview Detects and diagnoses errors in static, stack and heap memory and in memory and resource leaks.

- Ccmalloc

  Author Armin Biere (armin@ira.uk.de)

  License GNU General Public License

  Platforms Various UNIX

  Location http://iseran.ira.uka.de/~armin/ccmalloc/

  Overview Can interface with `gdb` to find memory leaks, multiple deallocations and memory corruptions in C or C++ programs.

- Enforcer

  Author Michael Sinz (Enforcer@sinz.org)

  License Free Software

  Platforms AmigaOS

  Location http://www.iam.com/amiga/enforcer.html

  Overview Sets up MMU tables to watch for illegal accesses to memory, such as the low page and non-existent pages.

- FDA (Free Debug Allocator)

  Author Thomas Helvey (tomh@inxpress.net)

  License GNU General Public License

  Platforms Linux, Windows

  Location http://www.debian.org/Packages/unstable/devel/fda.html

  Overview Provides routines that can be plugged in to replace `malloc()`, `calloc()`, `realloc()` and `free()`.

- Fortify

  Author Simon Bullen (sbullen@cybergraphic.com.au)

  License Free Software

  Platforms AmigaOS

  Location http://wuarchive.wustl.edu/~aminet/dirs/dev_c.html

  Overview Provides a fortified shell for memory allocations, trapping memory leaks, writes beyond and before memory blocks and writes to freed memory.

- GC (Garbage Collector)

  Author Hans-J. Boehm (boehm@acm.org)

  License Free Software

  Platforms Various UNIX, AmigaOS, MS-DOS, Windows, MacOS

  Location http://www.hpl.hp.com/personal/Hans_Boehm/gc/

  Overview A general-purpose, garbage-collecting storage allocator that is intended to be used as a plug-in replacement for `malloc()`, but can also be used to detect memory leaks.

- Great Circle

  Author Geodesic Systems (info@geodesic.com)

  License Commercial Software

  Platforms Various UNIX, Windows

  Location http://www.geodesic.com/

  Overview Provides complete heap profiling, allowing programmers to see what parts of a program are using the most memory with symbolic stack tracing.

- HeapAgent

  Author MicroQuill (info@microquill.com)

  License Commercial Software

  Platforms Windows

  Location http://www.microquill.com/

  Overview Instruments the heap to provide heap error detection without the need to recompile any source code.

- Insure++

  Author ParaSoft (info@parasoft.com)

  License Commercial Software

  Platforms Various UNIX, Windows

  Location http://www.parasoft.com/

  Overview Uses Source Code Instrumentation and Runtime Pointer Tracking technologies to pinpoint memory corruption, memory leaks, operations on unrelated pointers and more.

- LeakTracer

  Author Erwin Andreasen (erwin@andreasen.org)

  License Free Software

  Platforms Various UNIX

  Location http://www.andreasen.org/LeakTracer/

  Overview Detects memory leaks in C++ programs by overriding `operator new` and `operator delete`.

- Malloc Debug Library

  Author Rammi (rammi@quincunx.escape.de)

  License Free Software

  Platforms Various UNIX

  Location http://www.escape.de/users/quincunx/rmdebug.html

Overview Implements wrappers for the normal heap handling functions.

- MCheck

  Author Ronald Veldema (rveldema@cs.vu.nl)

  License GNU General Public License

  Platforms Linux

  Location http://www.cs.vu.nl/~rveldema/mcheck/mcheck.html

  Overview A memory usage and malloc checker for C and C++. Comes with a Java application for browsing the trace files produced.

- MemCheck

  Author Stratosware Corporation (info@stratosware.com)

  License Commercial Software

  Platforms Windows

  Location http://www.stratosware.com/

  Overview Detects various run-time errors related to operating system resources and provides information on memory leaks.

- MemDebug

  Author Rene Schmit (rene.schmit@crpht.lu)

  License Free Software

  Platforms Various UNIX, MS-DOS, Windows, MacOS

  Location ftp://ftp.crpht.lu/pub/sources/memdebug/

  Overview Provides memory management error detection, memory usage error detection, memory usage profiling and error simulation.

- Memory Advisor

  Author PLATINUM Technology (info@platinum.com)

  License Commercial Software

  Platforms Various UNIX

  Location http://www.platinum.com/

  Overview Disassembles an object module into system-independent assembler code, inserts error checking instructions, then re-assembles the code. Can also replace existing malloc libraries in order to provide greater error checking.

- Memprof

  Author Owen Taylor (otaylor@redhat.com)

  License GNU General Public License

Platforms Linux

Location http://people.redhat.com/otaylor/memprof/

Overview A tool for profiling memory usage and detecting memory leaks.

- MemWatch

  Author Johan Lindh (johan@link-data.com)

  License Free Software

  Platforms Various UNIX, Windows

  Location http://www.link-data.com/

  Overview A fault-tolerant memory leak and corruption detection tool.

- MemWatch

  Author Doug Walker (walker@unx.sas.com)

  License Free Software

  Platforms AmigaOS

  Location http://wuarchive.wustl.edu/~aminet/dirs/dev_debug.html

  Overview Provides replacement memory allocation routines for adding lots of memory debugging features that you link into your program.

- MM (Shared Memory Library)

  Author Ralf S. Engelschall (rse@engelschall.com)

  License Free Software

  Platforms Various UNIX, Windows

  Location http://www.engelschall.com/sw/mm/

  Overview Simplifies the usage (and can help debug) the use of shared memory between related processes.

- Mmalloc

  Author Mike Haertel (mike@ai.mit.edu) and Fred Fish (fnf@cygnus.com)

  License GNU General Public License

  Platforms Various UNIX

  Location http://www.gnu.org/

  Overview Uses `mmap()` to allocate separate pools of memory which can be mapped onto files for later reuse.

- MPR

  Author Taj Khattra (taj.khattra@pobox.com)

  License Free Software

Platforms Linux

Location http://metalab.unc.edu/pub/Linux/devel/lang/c/mpr-2.0.tar.gz

Overview Attempts to find memory leaks in C/C++ programs by writing a log file during program execution, which can then be processed for obtaining further information.

- Mprof

  Author Ben Zorn (zorn@cs.colorado.edu)

  License Free Software

  Platforms Various UNIX

  Location ftp://gatekeeper.dec.com/pub/misc/mprof-3.0.tar.Z

  Overview Profiles the dynamic memory allocation behaviour of programs by logging details for each function than makes a memory allocation, including call stack tracebacks.

- MuForce

  Author Thomas Richter (thor@einstein.math.tu-berlin.de)

  License Free Software

  Platforms AmigaOS

  Location http://www.math.tu-berlin.de/~thor/thor/index.html

  Overview Uses the MMU to monitor the system for any writes to non-existent memory and reports them over the serial port or any other output stream.

- MuGuardianAngel

  Author Thomas Richter (thor@einstein.math.tu-berlin.de)

  License Free Software

  Platforms AmigaOS

  Location http://www.math.tu-berlin.de/~thor/thor/index.html

  Overview An extension to the MuForce program which protects free memory and detects all illegal memory accesses.

- MuLib

  Author Thomas Richter (thor@einstein.math.tu-berlin.de)

  License Free Software

  Platforms AmigaOS

  Location http://www.math.tu-berlin.de/~thor/thor/index.html

  Overview Provides access to the MMU in modern Amigas so that features such as virtual memory can be implemented.

- Mungwall

  Author Commodore-Amiga, Inc. (info@amiga.de)

  License Free Software

  Platforms AmigaOS

  Location http://wuarchive.wustl.edu/~aminet/dirs/dev_debug.html

  Overview Patches the system to check for free memory corruption.

- Plumber

  Author Owen O'Malley (omalley@ics.uci.edu)

  License GNU General Public License

  Platforms Linux, Solaris, SunOS

  Location http://www.ics.uci.edu/~softtest/plumber.html

  Overview A tool that replaces the normal Ada and C/C++ dynamic memory allocation functions and detects unfreed memory blocks.

- Purify

  Author Rational Software (info@rational.com)

  License Commercial Software

  Platforms Various UNIX, Windows

  Location http://www.rational.com/

  Overview Uses Object Code Insertion technology to provide run-time error checking and memory leak detection.

- QC

  Author Onyx Technology (sales@onyx-tech.com)

  License Commercial Software

  Platforms MacOS

  Location http://www.onyx-tech.com/

  Overview Runs in the background as a control panel and detects various memory errors which can then be caught and run under a debugger.

- Wipeout

  Author Olaf Barthel (olsen@sourcery.han.de)

  License Free Software

  Platforms AmigaOS

  Location http://wuarchive.wustl.edu/~aminet/dirs/dev_debug.html

  Overview Runs in the background checking free memory for corruption.

- YAMD (Yet Another Malloc Debugger)

  Author Nate Eldredge (neldredge@hmc.edu)

  License GNU General Public License

  Platforms Linux, DOS

  Location http://www3.hmc.edu/~neldredge/yamd/

  Overview A tool for finding bugs related to dynamic memory allocation in C and C++, and includes paging mechanisms to catch bugs immediately.

- ZeroFault

  Author The Kernel Group (info@zerofault.com)

  License Commercial Software

  Platforms AIX UNIX

  Location http://www.zerofault.com/

  Overview Uses run-time emulator technology to provide run-time error checking and memory leak detection.

However, before you try out any of the above software, there may already be a malloc library with debugging support on your system that might be suitable for solving your problem. For example, on Solaris 7 the following libraries are available:

malloc(3c) Trade-off between performance and efficiency.

malloc(3x)
: Slower performance, space-efficient.

bsdmalloc(3x)
: Better performance, space-inefficient.

mtmalloc(3t)
: Thread-safe memory allocator.

mapmalloc(3x)
: Uses `mmap()` instead of `sbrk()` to allocate heap space.

watchmalloc(3x)
: Uses watch point areas to check for overflows.
