1 Introduction

The C language provides no built-in facilities for performing such common operations as input/output, memory management, string manipulation, and the like. Instead, these facilities are defined in a standard *library*, which you compile and link with your programs.

The GNU C library, described in this document, defines all of the library functions that are specified by the ANSI C standard, as well as additional features specific to POSIX and other derivatives of the Unix operating system, and extensions specific to the GNU system.

The purpose of this manual is to tell you how to use the facilities of the GNU library. We have mentioned which features belong to which standards to help you identify things that are potentially nonportable to other systems. But the emphasis on this manual is not on strict portability.

1.1 Getting Started

This manual is written with the assumption that you are at least somewhat familiar with the C programming language and basic programming concepts. Specifically, familiarity with ANSI standard C (see Section 1.2.1 [ANSI C], page 2), rather than "traditional" pre-ANSI C dialects, is assumed.

The GNU C library includes several header files, each of which provides definitions and declarations for a group of related facilities; this information is used by the C compiler when processing your program. For example, the header file 'stdio.h' declares facilities for performing input and output, and the header file 'string.h' declares string processing utilities. The organization of this manual generally follows the same division as the header files.

If you are reading this manual for the first time, you should read all of the introductory material and skim the remaining chapters. There are a lot of functions in the GNU C library and it's not realistic to expect that you will be able to remember exactly how to use each and every one of them. It's more important to become generally familiar with the kinds of facilities that the library provides, so that when you are writing your programs you can recognize when to make use of library functions, and where in this manual you can find more specific information about them.

1.2 Standards and Portability

This section discusses the various standards and other sources that the GNU C library is based upon. These sources include the ANSI C and POSIX standards, and the System V and Berkeley Unix implementations.

The primary focus of this manual is to tell you how to make effective use of the GNU library facilities. But if you are concerned about making your programs compatible with these standards, or portable to operating systems other than GNU, this can affect how you use the library. This section gives you an overview of these standards, so that you will know what they are when they are mentioned in other parts of the manual.

See Appendix B [Library Summary], page 583, for an alphabetical list of the functions and other symbols provided by the library. This list also states which standards each function or symbol comes from.

1.2.1 ANSI C

The GNU C library is compatible with the C standard adopted by the American National Standards Institute (ANSI): American National Standard X3.159-1989—"ANSI C". The header files and library facilities that make up the GNU library are a superset of those specified by the ANSI C standard.

If you are concerned about strict adherence to the ANSI C standard, you should use the '-ansi' option when you compile your programs with the GNU C compiler. This tells the compiler to define only ANSI standard features from the library header files, unless you explicitly ask for additional features. See Section 1.3.4 [Feature Test Macros], page 9, for information on how to do this.

Being able to restrict the library to include only ANSI C features is important because ANSI C puts limitations on what names can be defined by the library implementation, and the GNU extensions don't fit these limitations. See Section 1.3.3 [Reserved Names], page 7, for more information about these restrictions.

This manual does not attempt to give you complete details on the differences between ANSI C and older dialects. It gives advice on how to write programs to work portably under multiple C dialects, but does not aim for completeness.

1.2.2 POSIX (The Portable Operating System Interface)

The GNU library is also compatible with the IEEE *POSIX* family of standards, known more formally as the *Portable Operating System Interface for Computer Environments*. POSIX is derived mostly from various versions of the Unix operating system.

The library facilities specified by the POSIX standard are a superset of those required by ANSI C; POSIX specifies additional features for ANSI C functions, as well as specifying new additional functions. In general, the additional requirements and functionality defined by the POSIX standard are aimed at providing lower-level support for a particular kind of operating system environment, rather than general programming language support which can run in many diverse operating system environments.

The GNU C library implements all of the functions specified in *IEEE Std 1003.1-1988*, the *POSIX System Application Program Interface*, commonly referred to as POSIX.1. The primary extensions to the ANSI C facilities specified by this standard include file system interface primitives (see Chapter 13 [File System Interface], page 233), device-specific terminal control functions (see Chapter 16 [Low-Level Terminal Interface], page 321), and process control functions (see Chapter 23 [Child Processes], page 481).

Some facilities from draft 11 of *IEEE Std 1003.2*, the *POSIX Shell and Utilities standard* (POSIX.2) are also implemented in the GNU library. These include utilities for dealing with regular expressions and other pattern matching facilities (see Chapter 9 [Pattern Matching], page 113).

1.2.3 Berkeley Unix

The GNU C library defines facilities from some other versions of Unix, specifically from the 4.2 BSD and 4.3 BSD Unix systems (also known as *Berkeley Unix*) and from *SunOS* (a popular 4.2 BSD derivative that includes some Unix System V functionality).

The BSD facilities include symbolic links (see Section 13.4 [Symbolic Links], page 240), the select function (see Section 12.6 [Waiting for I/O], page 215), the BSD signal functions (see Section 21.9 [BSD Signal Handling], page 458), and sockets (see Chapter 15 [Sockets], page 269).

1.2.4 SVID (The System V Interface Description)

The System V Interface Description (SVID) is a document describing the AT&T Unix System V operating system. It is to some extent a superset of the POSIX standard (see Section 1.2.2 [POSIX], page 3).

The GNU C library defines some of the facilities required by the SVID that are not also required by the ANSI or POSIX standards, for compatibility with System V Unix and other Unix systems (such as SunOS) which include these facilities. However, many of the more obscure and less generally useful facilities required by the SVID are not included. (In fact, Unix System V itself does not provide them all.)

Incomplete: Are there any particular System V facilities that ought to be mentioned specifically here?

1.3 Using the Library

This section describes some of the practical issues involved in using the GNU C library.

1.3.1 Header Files

Libraries for use by C programs really consist of two parts: header files that define types and macros and declare variables and functions; and the actual library or archive that contains the definitions of the variables and functions.

(Recall that in C, a declaration merely provides information that a function or variable exists and gives its type. For a function declaration, information about the types of its arguments might be provided as well. The purpose of declarations is to allow the compiler to correctly process references to the declared variables and functions. A definition, on the other hand, actually allocates storage for a variable or says what a function does.)

In order to use the facilities in the GNU C library, you should be sure that your program source files include the appropriate header files. This is so that the compiler has declarations of these facilities available and can correctly process references to them. Once your program has been compiled, the linker resolves these references to the actual definitions provided in the archive file.

Header files are included into a program source file by the '#include' preprocessor directive. The C language supports two forms of this directive; the first,

#include "header"

is typically used to include a header file *header* that you write yourself; this would contain definitions and declarations describing the interfaces between the different parts of your particular application. By contrast,

#include <file.h>

is typically used to include a header file 'file.h' that contains definitions and declarations for a standard library. This file would normally be installed in a standard place by your system administrator. You should use this second form for the C library header files.

Typically, '#include' directives are placed at the top of the C source file, before any other code. If you begin your source files with some comments explaining what the code in the file does (a good idea), put the '#include' directives immediately afterwards, following the feature test macro definition (see Section 1.3.4 [Feature Test Macros], page 9).

For more information about the use of header files and '#include' directives, see section "Header Files" in *The GNU C Preprocessor Manual*.

The GNU C library provides several header files, each of which contains the type and macro definitions and variable and function declarations for a group of related facilities. This means that your programs may need to include several header files, depending on exactly which facilities you are using.

Some library header files include other library header files automatically. However, as a matter of programming style, you should not rely on this; it is better to explicitly include all the header files required for the library facilities you are using. The GNU C library header files have been written in such a way that it doesn't matter if a header file is accidentally included more than once; including a header file a second time has no effect. Likewise, if your program needs to include multiple header files, the order in which they are included doesn't matter.

Compatibility Note: Inclusion of standard header files in any order and any number of times works in any ANSI C implementation. However, this has traditionally not been the case in many older C implementations.

Strictly speaking, you don't have to include a header file to use a function it declares; you could declare the function explicitly yourself, according to the specifications in this manual. But it is usually better to include the header file because it may define types and macros that are not otherwise available and because it may define more efficient macro replacements for some functions. It is also a sure way to have the correct declaration.

1.3.2 Macro Definitions of Functions

If we describe something as a function in this manual, it may have a macro definition as well. This normally has no effect on how your program runs—the macro definition does the same thing as the function would. In particular, macro equivalents for library functions evaluate arguments exactly once, in the same way that a function call would. The main reason for these macro definitions is that sometimes they can produce an inline expansion that is considerably faster than an actual function call.

Taking the address of a library function works even if it is also defined as a macro. This is because, in this context, the name of the function isn't followed by the left parenthesis that is syntactically necessary to recognize the a macro call.

You might occasionally want to avoid using the a macro definition of a function—perhaps to make your program easier to debug. There are two ways you can do this:

- You can avoid a macro definition in a specific use by enclosing the name of the function in parentheses. This works because the name of the function doesn't appear in a syntactic context where it is recognizable as a macro call.
- You can suppress any macro definition for a whole source file by using the '#undef' preprocessor directive, unless otherwise stated explicitly in the description of that facility.

For example, suppose the header file 'stdlib.h' declares a function named abs with

```
extern int abs (int);
```

and also provides a macro definition for abs. Then, in:

```
#include <stdlib.h>
int f (int *i) { return (abs (++*i)); }
```

the reference to abs might refer to either a macro or a function. On the other hand, in each of the following examples the reference is to a function and not a macro.

```
#include <stdlib.h>
int g (int *i) { return ((abs)(++*i)); }
#undef abs
int h (int *i) { return (abs (++*i)); }
```

Since macro definitions that double for a function behave in exactly the same way as the actual function version, there is usually no need for any of these methods. In fact, removing macro definitions usually just makes your program slower.

1.3.3 Reserved Names

The names of all library types, macros, variables and functions that come from the ANSI C standard are reserved unconditionally; your program **may not** redefine these names. All other library names are reserved if your programs explicitly includes the header file that defines or declares them. There are several reasons for these restrictions:

- Other people reading your code could get very confused if you were using a function named exit to do something completely different from what the standard exit function does, for example. Preventing this situation helps to make your programs easier to understand and contributes to modularity and maintainability.
- It avoids the possibility of a user accidentally redefining a library function that is called by other library functions. If redefinition were allowed, those other functions would not work properly.
- It allows the compiler to do whatever special optimizations it pleases on calls to these functions, without the possibility that they may have been redefined by the user. Some library facilities, such as those for dealing with variadic arguments (see Section A.2 [Variadic Functions], page 564) and non-local exits (see Chapter 20 [Non-Local Exits], page 397), actually require a

considerable amount of cooperation on the part of the C compiler, and implementationally it might be easier for the compiler to treat these as built-in parts of the language.

In addition to the names documented in this manual, reserved names include all external identifiers (global functions and variables) that begin with an underscore ('_') and all identifiers regardless of use that begin with either two underscores or an underscore followed by a capital letter are reserved names. This is so that the library and header files can define functions, variables, and macros for internal purposes without risk of conflict with names in user programs.

Some additional classes of identifier names are reserved for future extensions to the C language. While using these names for your own purposes right now might not cause a problem, they do raise the possibility of conflict with future versions of the C standard, so you should avoid these names.

- Names beginning with a capital 'E' followed a digit or uppercase letter may be used for additional error code names. See Chapter 2 [Error Reporting], page 15.
- Names that begin with either 'is' or 'to' followed by a lowercase letter may be used for additional character testing and conversion functions. See Chapter 4 [Character Handling], page 61.
- Names that begin with 'LC_' followed by an uppercase letter may be used for additional macros specifying locale attributes. See Chapter 7 [Locales], page 97.
- Names of all existing mathematics functions (see Chapter 17 [Mathematics], page 349) suffixed with 'f' or 'l' are reserved for corresponding functions that operate on float or long double arguments, respectively.
- Names that begin with 'SIG' followed by an uppercase letter are reserved for additional signal names. See Section 21.2 [Standard Signals], page 406.
- Names that begin with 'SIG_' followed by an uppercase letter are reserved for additional signal actions. See Section 21.3.1 [Basic Signal Handling], page 416.
- Names beginning with 'str', 'mem', or 'wcs' followed by a lowercase letter are reserved for additional string and array functions. See Chapter 5 [String and Array Utilities], page 65.
- Names that end with '_t' are reserved for additional type names.

In addition, some individual header files reserve names beyond those that they actually define. You only need to worry about these restrictions if your program includes that particular header file.

• The header file 'dirent.h' reserves names prefixed with 'd_'.

- The header file 'fcntl.h' reserves names prefixed with 'l_', 'F_', 'O_', and 'S_'.
- The header file 'grp.h' reserves names prefixed with 'gr_'.
- The header file 'limits.h' reserves names suffixed with '_MAX'.
- The header file 'pwd.h' reserves names prefixed with 'pw_'.
- The header file 'signal.h' reserves names prefixed with 'sa_' and 'SA_'.
- The header file 'sys/stat.h' reserves names prefixed with 'st_' and 'S_'.
- The header file 'sys/times.h' reserves names prefixed with 'tms_'.
- The header file 'termios.h' reserves names prefixed with 'c_', 'V', 'I', 'O', and 'TC'; and names prefixed with 'B' followed by a digit.

1.3.4 Feature Test Macros

The exact set of features available when you compile a source file is controlled by which feature test macros you define.

If you compile your programs using 'gcc-ansi', you get only the ANSI C library features, unless you explicitly request additional features by defining one or more of the feature macros. See section "Options" in *The GNU CC Manual*, for more information about GCC options.

You should define these macros by using '#define' preprocessor directives at the top of your source code files. You could also use the '-D' option to GCC, but it's better if you make the source files indicate their own meaning in a self-contained way.

_POSIX_SOURCE Macro

If you define this macro, then the functionality from the POSIX.1 standard (IEEE Standard 1003.1) is available, as well as all of the ANSI C facilities.

_POSIX_C_SOURCE

Macro

If you define this macro with a value of 1, then the functionality from the POSIX.1 standard (IEEE Standard 1003.1) is made available. If you define this macro with a value of 2, then both the functionality from the POSIX.1 standard and the functionality from the POSIX.2 standard (IEEE Standard 1003.2) are made available. This is in addition to the ANSI C facilities.

Macro

10

If you define this macro, functionality derived from 4.3 BSD Unix is included as well as the ANSI C, POSIX.1, and POSIX.2 material.

Some of the features derived from 4.3 BSD Unix conflict with the corresponding features specified by the POSIX.1 standard. If this macro is defined, the 4.3 BSD definitions take precedence over the POSIX definitions.

_SVID_SOURCE Macro

If you define this macro, functionality derived from SVID is included as well as the ANSI C, POSIX.1, and POSIX.2 material.

_GNU_SOURCE Macro

If you define this macro, everything is included: ANSI C, POSIX.1, POSIX.2, BSD, SVID, and GNU extensions. In the cases where POSIX.1 conflicts with BSD, the POSIX definitions take precedence.

If you want to get the full effect of _GNU_SOURCE but make the BSD definitions take precedence over the POSIX definitions, use this sequence of definitions:

#define _GNU_SOURCE #define _BSD_SOURCE #define _SVID_SOURCE

_BSD_SOURCE

We recommend you use _GNU_SOURCE in new programs. If you don't specify the '-ansi' option to GCC and don't define any of these macros explicitly, the effect as the same as defining _GNU_ SOURCE.

When you define a feature test macro to request a larger class of features, it is harmless to define in addition a feature test macro for a subset of those features. For example, if you define _POSIX_ C_SOURCE, then defining _POSIX_SOURCE as well has no effect. Likewise, if you define _GNU_SOURCE, then defining either _POSIX_SOURCE or _POSIX_C_SOURCE or _SVID_SOURCE as well has no effect.

Note, however, that the features of _BSD_SOURCE are not a subset of any of the other feature test macros supported. This is because it defines BSD features that take precedence over the POSIX features that are requested by the other macros. For this reason, defining _BSD_SOURCE in addition to the other feature test macros does have an effect: it causes the BSD features to take priority over the conflicting POSIX features.

1.4 Roadmap to the Manual

Here is an overview of the contents of the remaining chapters of this manual.

- Chapter 2 [Error Reporting], page 15, describes how errors detected by the library are reported.
- Appendix A [Language Features], page 563, contains information about library support for standard parts of the C language, including things like the sizeof operator and the symbolic constant NULL, and how to write functions accepting variable numbers of arguments.
- Chapter 3 [Memory Allocation], page 29, describes the GNU library's facilities for dynamic allocation of storage. If you do not know in advance how much storage your program needs, you can allocate it dynamically instead, and manipulate it via pointers.
- Chapter 4 [Character Handling], page 61, contains information about character classification functions (such as isspace) and functions for performing case conversion.
- Chapter 5 [String and Array Utilities], page 65, has descriptions of functions for manipulating strings (null-terminated character arrays) and general byte arrays, including operations such as copying and comparison.
- Chapter 6 [Extended Characters], page 83, contains information about manipulating characters and strings using character sets larger than will fit in the usual char data type.
- Chapter 7 [Locales], page 97, describes how selecting a particular country or language affects the behavior of the library. For example, the locale affects collation sequences for strings and how monetary values are formatted.
- Chapter 8 [Searching and Sorting], page 107, contains information about functions for searching and sorting arrays. You can use these functions on any kind of array by providing an appropriate comparison function.
- Chapter 10 [I/O Overview], page 131, gives an overall look at the input and output facilities in the library, and contains information about basic concepts such as file names.
- Chapter 11 [I/O on Streams], page 139, describes I/O operations involving streams (or FILE * objects). These are the normal C library functions from 'stdio.h'.
- Chapter 12 [Low-Level I/O], page 203, contains information about I/O operations on file descriptors. File descriptors are a lower-level mechanism specific to the Unix family of operating systems.
- Chapter 13 [File System Interface], page 233, has descriptions of operations on entire files, such as functions for deleting and renaming them and for creating new directories. This chapter also contains information about how you can access the attributes of a file, such as its owner and file protection modes.
- Chapter 14 [Pipes and FIFOs], page 263, contains information about simple interprocess communication mechanisms. Pipes allow communication between two related processes (such as

- between a parent and child), while FIFOs allow communication between processes sharing a common file system.
- Chapter 15 [Sockets], page 269, describes a more complicated interprocess communication mechanism that allows processes running on different machines to communicate over a network. This chapter also contains information about Internet host addressing and how to use the system network databases, such as '/etc/hosts'.
- Chapter 16 [Low-Level Terminal Interface], page 321, describes how you can change the attributes of a terminal device. If you want to disable echo of characters typed by the user, for example, read this chapter.
- Section A.1 [Consistency Checking], page 563, contains information about a simple debugging mechanism. You can put assertions in your code, and diagnostic messages are printed if the test fails.
- Chapter 17 [Mathematics], page 349, contains information about the math library functions. These include things like random-number generators and remainder functions on integers as well as the usual trigonometric and exponential functions on floating-point numbers.
- Chapter 19 [Date and Time], page 371, describes functions for measuring both calendar time and CPU time, as well as functions for setting alarms and timers.
- Chapter 20 [Non-Local Exits], page 397, contains descriptions of the setjmp and longjmp functions.
- Chapter 21 [Signal Handling], page 403, tells you all about signals—what they are, how to establish a handler that is called when a particular kind of signal is delivered, and how to prevent signals from arriving during critical sections of your program.
- Chapter 23 [Child Processes], page 481, contains information about how to start new processes and run programs.
- Chapter 22 [Process Startup], page 463, tells how your programs can access their command-line arguments and environment variables.
- Chapter 24 [Job Control], page 495, describes functions for manipulating process groups. This material is probably only of interest if you are writing a shell.
- Section 25.12 [User Database], page 533, and Section 25.13 [Group Database], page 536, tell you how to access the system user and group databases.
- Chapter 26 [System Information], page 541, describes functions for getting information about the hardware and software configuration your program is executing under.
- Section A.5.2 [Range of Type], page 574, contains information about parameters that characterize the sizes of integer and floating-point types used by the particular C implementation that your program has been compiled with. Most of these parameters are provided for compatibility with ANSI C.
- Chapter 27 [System Configuration], page 545, tells you how you can get information about various operating system limits. Most of these parameters are provided for compatibility with POSIX.

If you already know the name of the facility you are interested in, you can look it up in Appendix B [Library Summary], page 583. This gives you a summary of its syntax and a pointer to where you can find a more detailed description. This appendix is particularly useful if you just want to verify the order and type of arguments to a function, for example.

14

2 Error Reporting

Many functions in the GNU C library detect and report error conditions, and sometimes your programs need to check for these error conditions. For example, when you open an input file, you should verify that the file was actually opened correctly, and print an error message or take other appropriate action if the call to the library function failed.

This chapter describes how the error reporting facility works. Your program should include the header file 'errno.h' to use this facility.

2.1 Checking for Errors

Most library functions return a special value to indicate that they have failed. The special value is typically -1, a null pointer, or a constant such as EOF that is defined for that purpose. But this return value tells you only that an error has occurred. To find out what kind of error it was, you need to look at the error code stored in the variable errno. This variable is declared in the header file 'errno.h'.

volatile int errno Variable

The variable errno contains the system error number. You can change the value of errno.

Since errno is declared volatile, it might be changed asynchronously by a signal handler; see Section 21.4 [Defining Handlers], page 425. However, a properly written signal handler saves and restores the value of errno, so you generally do not need to worry about this possibility except when writing signal handlers.

The initial value of errno at program startup is zero. Many library functions are guaranteed to set it to certain nonzero values when they encounter certain kinds of errors. These error conditions are listed for each function. These functions do not change errno when they succeed; thus, the value of errno after a successful call is not necessarily zero, and you should not use errno to determine whether a call failed. The proper way to do that is documented for each function. If the call the failed, you can examine errno.

Many library functions can set errno to a nonzero value as a result of calling other library functions which might fail. You should assume that any library function might alter errno.

Portability Note: ANSI C specifies **errno** as a "modifiable lvalue" rather than as a variable, permitting it to be implemented as a macro. For example, its expansion might involve a function call, like ***_errno** (). In fact, that is what it is on the GNU system itself. The GNU library, on non-GNU systems, does whatever is right for the particular system.

There are a few library functions, like sqrt and atan, that return a perfectly legitimate value in case of an error, but also set errno. For these functions, if you want to check to see whether an error occurred, the recommended method is to set errno to zero before calling the function, and then check its value afterward.

All the error codes have symbolic names; they are macros defined in 'errno.h'. The names start with 'E' and an upper-case letter or digit; you should consider names of this form to be reserved names. See Section 1.3.3 [Reserved Names], page 7.

The error code values are all positive integers and are all distinct. (Since the values are distinct, you can use them as labels in a switch statement, for example.) Your program should not make any other assumptions about the specific values of these symbolic constants.

The value of errno doesn't necessarily have to correspond to any of these macros, since some library functions might return other error codes of their own for other situations. The only values that are guaranteed to be meaningful for a particular library function are the ones that this manual lists for that function.

On non-GNU systems, almost any system call can return EFAULT if it is given an invalid pointer as an argument. Since this could only happen as a result of a bug in your program, and since it will not happen on the GNU system, we have saved space by not mentioning EFAULT in the descriptions of individual functions.

2.2 Error Codes

The error code macros are defined in the header file 'erroo.h'. All of them expand into integer constant values. Some of these error codes can't occur on the GNU system, but they can occur using the GNU library on other systems.

int EPERM Macro

Operation not permitted; only the owner of the file (or other resource) or processes with special privileges can perform the operation.

int ENOENT Macro

No such file or directory. This is a "file doesn't exist" error for ordinary files that are referenced in contexts where they are expected to already exist.

int ESRCH Macro

No process matches the specified process ID.

int EINTR Macro

Interrupted function call; an asynchronous signal occurred and prevented completion of the call. When this happens, you should try the call again.

You can choose to have functions resume after a signal that is handled, rather than failing with EINTR; see Section 21.5 [Interrupted Primitives], page 438.

int EIO Macro

Input/output error; usually used for physical read or write errors.

int ENXIO Macro

No such device or address. Typically, this means that a file representing a device has been installed incorrectly, and the system can't find the right kind of device driver for it.

int E2BIG Macro

Argument list too long; used when the arguments passed to a new program being executed with one of the exec functions (see Section 23.5 [Executing a File], page 485) occupy too much memory space. This condition never arises in the GNU system.

18 The GNU C Library

int ENOEXEC Macro

Invalid executable file format. This condition is detected by the exec functions; see Section 23.5 [Executing a File], page 485.

int EBADF Macro

Bad file descriptor; for example, I/O on a descriptor that has been closed or reading from a descriptor open only for writing (or vice versa).

int ECHILD Macro

There are no child processes. This error happens on operations that are supposed to manipulate child processes, when there aren't any processes to manipulate.

int EDEADLK Macro

Deadlock avoided; allocating a system resource would have resulted in a deadlock situation. For an example, See Section 12.11 [File Locks], page 226.

int ENOMEM Macro

No memory available. The system cannot allocate more virtual memory because its capacity is full.

int EACCES Macro

Permission denied; the file permissions do not allow the attempted operation.

int EFAULT Macro

Bad address; an invalid pointer was detected.

int ENOTBLK Macro

A file that isn't a block special file was given in a situation that requires one. For example, trying to mount an ordinary file as a file system in Unix gives this error.

int EBUSY Macro

Resource busy; a system resource that can't be shared is already in use. For example, if you try to delete a file that is the root of a currently mounted filesystem, you get this error.

int EEXIST Macro

File exists; an existing file was specified in a context where it only makes sense to specify a new file.

int EXDEV Macro

An attempt to make an improper link across file systems was detected.

int ENODEV Macro

The wrong type of device was given to a function that expects a particular sort of device.

int ENOTDIR Macro

A file that isn't a directory was specified when a directory is required.

int EISDIR Macro

File is a directory; attempting to open a directory for writing gives this error.

int EINVAL Macro

Invalid argument. This is used to indicate various kinds of problems with passing the wrong argument to a library function.

int ENFILE Macro

There are too many distinct file openings in the entire system. Note that any number of linked channels count as just one file opening; see Section 12.5.1 [Linked Channels], page 213.

int EMFILE Macro

The current process has too many files open and can't open any more. Duplicate descriptors do count toward this limit.

int ENOTTY Macro

Inappropriate I/O control operation, such as trying to set terminal modes on an ordinary file.

20 The GNU C Library

int ETXTBSY Macro

An attempt to execute a file that is currently open for writing, or write to a file that is currently being executed. (The name stands for "text file busy".) This is not an error in the GNU system; the text is copied as necessary.

int EFBIG Macro

File too big; the size of a file would be larger than allowed by the system.

int ENOSPC Macro

No space left on device; write operation on a file failed because the disk is full.

int ESPIPE Macro

Invalid seek operation (such as on a pipe).

int EROFS Macro

An attempt was made to modify a file on a read-only file system.

int EMLINK Macro

Too many links; the link count of a single file is too large.

int EPIPE Macro

Broken pipe; there is no process reading from the other end of a pipe. Every library function that returns this error code also generates a SIGPIPE signal; this signal terminates the program if not handled or blocked. Thus, your program will never actually see EPIPE unless it has handled or blocked SIGPIPE.

int EDOM Macro

Domain error; used by mathematical functions when an argument value does not fall into the domain over which the function is defined.

int ERANGE Macro

Range error; used by mathematical functions when the result value is not representable because of overflow or underflow.

int EAGAIN Macro

Resource temporarily unavailable; the call might work if you try again later. Only fork returns error code EAGAIN for such a reason.

int EWOULDBLOCK

Macro

An operation that would block was attempted on an object that has non-blocking mode selected.

Portability Note: In 4.4BSD and GNU, EWOULDBLOCK and EAGAIN are the same. Earlier versions of BSD (see Section 1.2.3 [Berkeley Unix], page 3) have two distinct codes, and use EWOULDBLOCK to indicate an I/O operation that would block on an object with non-blocking mode set, and EAGAIN for other kinds of errors.

int EINPROGRESS

Macro

An operation that cannot complete immediately was initiated on an object that has non-blocking mode selected.

int EALREADY Macro

An operation is already in progress on an object that has non-blocking mode selected.

int ENOTSOCK Macro

A file that isn't a socket was specified when a socket is required.

int EDESTADDRREQ

Macro

No destination address was supplied on a socket operation.

int EMSGSIZE Macro

The size of a message sent on a socket was larger than the supported maximum size.

int EPROTOTYPE

Macro

The socket type does not support the requested communications protocol.

int ENOPROTOOPT

Macro

You specified a socket option that doesn't make sense for the particular protocol being used by the socket. See Section 15.11 [Socket Options], page 316.

int EPROTONOSUPPORT

Macro

The socket domain does not support the requested communications protocol. See Section 15.7.1 [Creating a Socket], page 292.

int ESOCKTNOSUPPORT

Macro

The socket type is not supported.

int EOPNOTSUPP

Macro

The operation you requested is not supported. Some socket functions don't make sense for all types of sockets, and others may not be implemented for all communications protocols.

int EPFNOSUPPORT

Macro

The socket communications protocol family you requested is not supported.

int EAFNOSUPPORT

Macro

The address family specified for a socket is not supported; it is inconsistent with the protocol being used on the socket. See Chapter 15 [Sockets], page 269.

int EADDRINUSE

Macro

The requested socket address is already in use. See Section 15.3 [Socket Addresses], page 271.

int EADDRNOTAVAIL

Macro

The requested socket address is not available; for example, you tried to give a socket a name that doesn't match the local host name. See Section 15.3 [Socket Addresses], page 271.

int ENETDOWN

Macro

A socket operation failed because the network was down.

int ENETUNREACH

Macro

A socket operation failed because the subnet containing the remost host was unreachable.

int ENETRESET Macro

A network connection was reset because the remote host crashed.

int ECONNABORTED

Macro

A network connection was aborted locally.

int ECONNRESET

Macro

A network connection was closed for reasons outside the control of the local host, such as by the remote machine rebooting.

int ENOBUFS Macro

The kernel's buffers for I/O operations are all in use.

int EISCONN Macro

You tried to connect a socket that is already connected. See Section 15.8.1 [Connecting], page 295.

int ENOTCONN Macro

The socket is not connected to anything. You get this error when you try to transmit data over a socket, without first specifying a destination for the data.

int ESHUTDOWN Macro

The socket has already been shut down.

int ETIMEDOUT Macro

A socket operation with a specified timeout received no response during the timeout period.

int ECONNREFUSED

Macro

A remote host refused to allow the network connection (typically because it is not running the requested service).

int ELOOP Macro

Too many levels of symbolic links were encountered in looking up a file name. This often indicates a cycle of symbolic links.

int ENAMETOOLONG

Macro

Filename too long (longer than PATH_MAX; see Section 27.6 [Limits for Files], page 553) or host name too long (in gethostname or sethostname; see Section 26.1 [Host Identification], page 541).

int EHOSTDOWN

Macro

The remote host for a requested network connection is down.

int EHOSTUNREACH

Macro

The remote host for a requested network connection is not reachable.

int ENOTEMPTY

Macro

Directory not empty, where an empty directory was expected. Typically, this error occurs when you are trying to delete a directory.

int EUSERS

Macro

The file quota system is confused because there are too many users.

int EDQUOT

Macro

The user's disk quota was exceeded.

int ESTALE

Macro

Stale NFS file handle. This indicates an internal confusion in the NFS system which is due to file system rearrangements on the server host. Repairing this condition usually requires unmounting and remounting the NFS file system on the local host.

int EREMOTE

Macro

An attempt was made to NFS-mount a remote file system with a file name that already specifies an NFS-mounted file. (This is an error on some operating systems, but we expect it to work properly on the GNU system, making this error code impossible.)

int ENOLCK

Macro

No locks available. This is used by the file locking facilities; see Section 12.11 [File Locks], page 226.

int ENOSYS Macro

Function not implemented. Some functions have commands or options defined that might not be supported in all implementations, and this is the kind of error you get if you request them and they are not supported.

int ED Macro

The experienced user will know what is wrong.

int EGRATUITOUS

Macro

This error code has no purpose.

2.3 Error Messages

The library has functions and variables designed to make it easy for your program to report informative error messages in the customary format about the failure of a library call. The functions strerror and perror give you the standard error message for a given error code; the variable program_invocation_short_name gives you convenient access to the name of the program that encountered the error.

char * strerror (int errnum)

Function

The strerror function maps the error code (see Section 2.1 [Checking for Errors], page 15) specified by the *errnum* argument to a descriptive error message string. The return value is a pointer to this string.

The value errnum normally comes from the variable errno.

You should not modify the string returned by **strerror**. Also, if you make subsequent calls to **strerror**, the string might be overwritten. (But it's guaranteed that no library function ever calls **strerror** behind your back.)

The function strerror is declared in 'string.h'.

void perror (const char *message)

Function

This function prints an error message to the stream stderr; see Section 11.2 [Standard Streams], page 139.

If you call perror with a *message* that is either a null pointer or an empty string, perror just prints the error message corresponding to erro, adding a trailing newline.

If you supply a non-null *message* argument, then **perror** prefixes its output with this string. It adds a colon and a space character to separate the *message* from the error string corresponding to **errno**.

The function perror is declared in 'stdio.h'.

strerror and perror produce the exact same message for any given error code; the precise text varies from system to system. On the GNU system, the messages are fairly short; there are no multi-line messages or embedded newlines. Each error message begins with a capital letter and does not include any terminating punctuation.

Compatibility Note: The strerror function is a new feature of ANSI C. Many older C systems do not support this function yet.

Many programs that don't read input from the terminal are designed to exit if any system call fails. By convention, the error message from such a program should start with the program's name, sans directories. You can find that name in the variable program_invocation_short_name; the full file name is stored the variable program_invocation_name:

char * program_invocation_name

Variable

This variable's value is the name that was used to invoke the program running in the current process. It is the same as argv[0].

char * program_invocation_short_name

Variable

This variable's value is the name that was used to invoke the program running in the current process, with directory names removed. (That is to say, it is the same as program_invocation_name minus everything up to the last slash, if any.)

Both program_invocation_name and program_invocation_short_name are set up by the system before main is called.

Portability Note: These two variables are GNU extensions. If you want your program to work with non-GNU libraries, you must save the value of argv[0] in main, and then strip off the directory names yourself. We added these extensions to make it possible to write self-contained error-reporting subroutines that require no explicit cooperation from main.

Here is an example showing how to handle failure to open a file correctly. The function open_sesame tries to open the named file for reading and returns a stream if successful. The fopen library function returns a null pointer if it couldn't open the file for some reason. In that situation, open_sesame constructs an appropriate error message using the strerror function, and terminates the program. If we were going to make some other library calls before passing the error code to strerror, we'd have to save it in a local variable instead, because those other library functions might overwrite errno in the meantime.

```
#include <errno.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
FILE *
open_sesame (char *name)
 FILE *stream;
  errno = 0;
  stream = fopen (name, "r");
  if (!stream) {
    fprintf (stderr, "%s: Couldn't open file %s; %s\n",
             program_invocation_short_name, name, strerror (errno));
    exit (EXIT_FAILURE);
  } else
    return stream;
}
```

28

3 Memory Allocation

The GNU system provides several methods for allocating memory space under explicit program control. They vary in generality and in efficiency.

- The malloc facility allows fully general dynamic allocation. See Section 3.3 [Unconstrained Allocation], page 30.
- Obstacks are another facility, less general than malloc but more efficient and convenient for stacklike allocation. See Section 3.4 [Obstacks], page 40.
- The function alloca lets you allocate storage dynamically that will be freed automatically. See Section 3.5 [Variable Size Automatic], page 54.

3.1 Dynamic Memory Allocation Concepts

Dynamic memory allocation is a technique in which programs determine as they are running where to store some information. You need dynamic allocation when the number of memory blocks you need, or how long you continue to need them, depends on the data you are working on.

For example, you may need a block to store a line read from an input file; since there is no limit to how long a line can be, you must allocate the storage dynamically and make it dynamically larger as you read more of the line.

Or, you may need a block for each record or each definition in the input data; since you can't know in advance how many there will be, you must allocate a new block for each record or definition as you read it.

When you use dynamic allocation, the allocation of a block of memory is an action that the program requests explicitly. You call a function or macro when you want to allocate space, and specify the size with an argument. If you want to free the space, you do so by calling another function or macro. You can do these things whenever you want, as often as you want.

3.2 Dynamic Allocation and C

The C language supports two kinds of memory allocation through the variables in C programs:

- Static allocation is what happens when you declare a static variable. Each static variable defines one block of space, of a fixed size. The space is allocated once, when your program is started, and is never freed.
- Automatic allocation happens when you declare an automatic variable, such as a function argument or a local variable. The space for an automatic variable is allocated when the compound statement containing the declaration is entered, and is freed when that compound statement is exited.

In GNU C, the length of the automatic storage can be an expression that varies. In other C implementations, it must be a constant.

Dynamic allocation is not supported by C variables; there is no storage class "dynamic", and there can never be a C variable whose value is stored in dynamically allocated space. The only way to refer to dynamically allocated space is through a pointer. Because it is less convenient, and because the actual process of dynamic allocation requires more computation time, programmers use dynamic allocation only when neither static nor automatic allocation will serve.

For example, if you want to allocate dynamically some space to hold a struct foobar, you cannot declare a variable of type struct foobar whose contents are the dynamically allocated space. But you can declare a variable of pointer type struct foobar * and assign it the address of the space. Then you can use the operators '*' and '->' on this pointer variable to refer to the contents of the space:

3.3 Unconstrained Allocation

The most general dynamic allocation facility is malloc. It allows you to allocate blocks of memory of any size at any time, make them bigger or smaller at any time, and free the blocks individually at any time (or never).

3.3.1 Basic Storage Allocation

To allocate a block of memory, call malloc. The prototype for this function is in 'stdlib.h'.

```
void * malloc (size_t size)
```

Function

This function returns a pointer to a newly allocated block size bytes long, or a null pointer if the block could not be allocated.

The contents of the block are undefined; you must initialize it yourself (or use calloc instead; see Section 3.3.5 [Allocating Cleared Space], page 35). Normally you would cast the value as a pointer to the kind of object that you want to store in the block. Here we show an example of doing so, and of initializing the space with zeros using the library function memset (see Section 5.4 [Copying and Concatenation], page 67):

```
struct foo *ptr;
...
ptr = (struct foo *) malloc (sizeof (struct foo));
if (ptr == 0) abort ();
memset (ptr, 0, sizeof (struct foo));
```

You can store the result of malloc into any pointer variable without a cast, because ANSI C automatically converts the type void * to another type of pointer when necessary. But the cast is necessary in contexts other than assignment operators or if you might want your code to run in traditional C.

Remember that when allocating space for a string, the argument to malloc must be one plus the length of the string. This is because a string is terminated with a null character that doesn't count in the "length" of the string but does need space. For example:

```
char *ptr;
...
ptr = (char *) malloc (length + 1);
```

See Section 5.1 [Representation of Strings], page 65, for more information about this.

3.3.2 Examples of malloc

If no more space is available, malloc returns a null pointer. You should check the value of every call to malloc. It is useful to write a subroutine that calls malloc and reports an error if the value is a null pointer, returning only if the value is nonzero. This function is conventionally called xmalloc. Here it is:

```
void *
xmalloc (size_t size)
{
  register void *value = malloc (size);
  if (value == 0)
    fatal ("virtual memory exhausted");
  return value;
}
```

Here is a real example of using malloc (by way of xmalloc). The function savestring will copy a sequence of characters into a newly allocated null-terminated string:

```
char *
savestring (const char *ptr, size_t len)
{
  register char *value = (char *) xmalloc (len + 1);
  memcpy (value, ptr, len);
  value[len] = 0;
  return value;
}
```

The block that malloc gives you is guaranteed to be aligned so that it can hold any type of data. In the GNU system, the address is always a multiple of eight; if the size of block is 16 or more, then the address is always a multiple of 16. Only rarely is any higher boundary (such as a page boundary) necessary; for those cases, use memalign or valloc (see Section 3.3.7 [Aligned Memory Blocks], page 36).

Note that the memory located after the end of the block is likely to be in use for something else; perhaps a block already allocated by another call to malloc. If you attempt to treat the block as longer than you asked for it to be, you are liable to destroy the data that malloc uses to keep track of its blocks, or you may destroy the contents of another block. If you have already allocated a block and discover you want it to be bigger, use realloc (see Section 3.3.4 [Changing Block Size], page 34).

3.3.3 Freeing Memory Allocated with malloc

When you no longer need a block that you got with malloc, use the function free to make the block available to be allocated again. The prototype for this function is in 'stdlib.h'.

```
void free (void *ptr)
```

Function

The free function deallocates the block of storage pointed at by ptr.

```
void cfree (void *ptr)
```

Function

This function does the same thing as free. It's provided for backward compatibility with SunOS; you should use free instead.

Freeing a block alters the contents of the block. Do not expect to find any data (such as a pointer to the next block in a chain of blocks) in the block after freeing it. Copy whatever you need out of the block before freeing it! Here is an example of the proper way to free all the blocks in a chain, and the strings that they point to:

```
struct chain
{
    struct chain *next;
    char *name;
}

void
free_chain (struct chain *chain)
{
    while (chain != 0)
    {
        struct chain *next = chain->next;
        free (chain->name);
        free (chain);
        chain = next;
    }
}
```

Occasionally, free can actually return memory to the operating system and make the process smaller. Usually, all it can do is allow a later later call to malloc to reuse the space. In the mean time, the space remains in your program as part of a free-list used internally by malloc.

There is no point in freeing blocks at the end of a program, because all of the program's space is given back to the system when the process terminates.

3.3.4 Changing the Size of a Block

Often you do not know for certain how big a block you will ultimately need at the time you must begin to use the block. For example, the block might be a buffer that you use to hold a line being read from a file; no matter how long you make the buffer initially, you may encounter a line that is longer.

You can make the block longer by calling realloc. This function is declared in 'stdlib.h'.

```
void * realloc (void *ptr, size_t newsize)
```

Function

The realloc function changes the size of the block whose address is ptr to be newsize.

Since the space after the end of the block may be in use, realloc may find it necessary to copy the block to a new address where more free space is available. The value of realloc is the new address of the block. If the block needs to be moved, realloc copies the old contents.

Like malloc, realloc may return a null pointer if no memory space is available to make the block bigger. When this happens, the original block is untouched; it has not been modified or relocated.

In most cases it makes no difference what happens to the original block when realloc fails, because the application program cannot continue when it is out of memory, and the only thing to do is to give a fatal error message. Often it is convenient to write and use a subroutine, conventionally called xrealloc, that takes care of the error message as xmalloc does for malloc:

```
void *
xrealloc (void *ptr, size_t size)
{
  register void *value = realloc (ptr, size);
  if (value == 0)
    fatal ("Virtual memory exhausted");
  return value;
}
```

You can also use realloc to make a block smaller. The reason you would do this is to avoid tying up a lot of memory space when only a little is needed. Making a block smaller sometimes necessitates copying it, so it can fail if no other space is available.

If the new size you specify is the same as the old size, realloc is guaranteed to change nothing and return the same address that you gave.

3.3.5 Allocating Cleared Space

The function calloc allocates memory and clears it to zero. It is declared in 'stdlib.h'.

```
void * calloc (size_t count, size_t eltsize)
```

Function

This function allocates a block long enough to contain a vector of *count* elements, each of size *eltsize*. Its contents are cleared to zero before calloc returns.

You could define calloc as follows:

```
void *
calloc (size_t count, size_t eltsize)
{
   size_t size = count * eltsize;
   void *value = malloc (size);
   if (value != 0)
      memset (value, 0, size);
   return value;
}
```

We rarely use calloc today, because it is equivalent to such a simple combination of other features that are more often used. It is a historical holdover that is not quite obsolete.

3.3.6 Efficiency Considerations for malloc

To make the best use of malloc, it helps to know that the GNU version of malloc always dispenses small amounts of memory in blocks whose sizes are powers of two. It keeps separate pools for each power of two. This holds for sizes up to a page size. Therefore, if you are free to choose the size of a small block in order to make malloc more efficient, make it a power of two.

Once a page is split up for a particular block size, it can't be reused for another size unless all the blocks in it are freed. In many programs, this is unlikely to happen. Thus, you can sometimes make a program use memory more efficiently by using blocks of the same size for many different purposes.

When you ask for memory blocks of a page or larger, malloc uses a different strategy; it rounds the size up to a multiple of a page, and it can coalesce and split blocks as needed.

The reason for the two strategies is that it is important to allocate and free small blocks as fast as possible, but speed is less important for a large block since the program normally spends a fair amount of time using it. Also, large blocks are normally fewer in number. Therefore, for large blocks, it makes sense to use a method which takes more time to minimize the wasted space.

3.3.7 Allocating Aligned Memory Blocks

The address of a block returned by malloc or realloc in the GNU system is always a multiple of eight. If you need a block whose address is a multiple of a higher power of two than that, use memalign or valloc. These functions are declared in 'stdlib.h'.

With the GNU library, you can use free to free the blocks that memalign and valloc return. That does not work in BSD, however—BSD does not provide any way to free such blocks.

void * memalign (size_t size, int boundary)

Function

The memalign function allocates a block of size bytes whose address is a multiple of boundary. The boundary must be a power of two! The function memalign works by calling malloc to allocate a somewhat larger block, and then returning an address within the block that is on the specified boundary.

void * valloc (size_t size)

Function

Using valloc is like using memalign and passing the page size as the value of the second argument.

3.3.8 Heap Consistency Checking

You can ask malloc to check the consistency of dynamic storage by using the mcheck function. This function is a GNU extension, declared in 'malloc.h'.

void mcheck (void (*abortfn) (void))

Function

Calling mcheck tells malloc to perform occasional consistency checks. These will catch things such as writing past the end of a block that was allocated with malloc.

The abort fn argument is the function to call when an inconsistency is found. If you supply a null pointer, the abort function is used.

It is too late to begin allocation checking once you have allocated anything with malloc. So mcheck does nothing in that case. The function returns -1 if you call it too late, and 0 otherwise (when it is successful).

The easiest way to arrange to call mcheck early enough is to use the option '-lmcheck' when you link your program.

3.3.9 Storage Allocation Hooks

The GNU C library lets you modify the behavior of malloc, realloc, and free by specifying appropriate hook functions. You can use these hooks to help you debug programs that use dynamic storage allocation, for example.

The hook variables are declared in 'malloc.h'.

__malloc_hook Variable

The value of this variable is a pointer to function that malloc uses whenever it is called. You should define this function to look like malloc; that is, like:

void *function (size_t size)

__realloc_hook Variable

The value of this variable is a pointer to function that realloc uses whenever it is called. You should define this function to look like realloc; that is, like:

void *function (void *ptr, size_t size)

38 The GNU C Library

__free_hook Variable

The value of this variable is a pointer to function that free uses whenever it is called. You should define this function to look like free; that is, like:

```
void function (void *ptr)
```

You must make sure that the function you install as a hook for one of these functions does not call that function recursively without restoring the old value of the hook first! Otherwise, your program will get stuck in an infinite recursion.

Here is an example showing how to use __malloc_hook properly. It installs a function that prints out information every time malloc is called.

```
static void *(*old_malloc_hook) (size_t);
static void *
my_malloc_hook (size_t size)
{
   void *result;
   __malloc_hook = old_malloc_hook;
   result = malloc (size);
   __malloc_hook = my_malloc_hook;
   printf ("malloc (%u) returns %p\n", (unsigned int) size, result);
   return result;
}
main ()
{
   ...
   old_malloc_hook = __malloc_hook;
   __malloc_hook = my_malloc_hook;
   ...
}
```

The mcheck function (see Section 3.3.8 [Heap Consistency Checking], page 36) works by installing such hooks.

3.3.10 Statistics for Storage Allocation with malloc

function and its associated data type are declared in 'malloc.h'; they are a GNU extension.

You can get information about dynamic storage allocation by calling the mstats function. This

struct mstats Data Type

This structure type is used to return information about the dynamic storage allocator. It contains the following members:

size_t bytes_total

This is the total size of memory managed by malloc, in bytes.

size_t chunks_used

This is the number of chunks in use. (The storage allocator internally gets chunks of memory from the operating system, and then carves them up to satisfy individual malloc requests; see Section 3.3.6 [Efficiency and Malloc], page 35.)

size_t bytes_used

This is the number of bytes in use.

size_t chunks_free

This is the number of chunks which are free – that is, that have been allocated by the operating system to your program, but which are not now being used.

size_t bytes_free

This is the number of bytes which are free.

struct mstats mstats (void)

Function

This function returns information about the current dynamic memory usage in a structure of type struct mstats.

3.3.11 Summary of malloc-Related Functions

Here is a summary of the functions that work with malloc:

void *malloc (size_t size)

Allocate a block of size bytes. See Section 3.3.1 [Basic Allocation], page 31.

The GNU C Library

void free (void *addr)

40

Free a block previously allocated by malloc. See Section 3.3.3 [Freeing after Malloc], page 33.

void *realloc (void *addr, size_t size)

Make a block previously allocated by malloc larger or smaller, possibly by copying it to a new location. See Section 3.3.4 [Changing Block Size], page 34.

void *calloc (size_t count, size_t eltsize)

Allocate a block of *count* * *eltsize* bytes using malloc, and set its contents to zero. See Section 3.3.5 [Allocating Cleared Space], page 35.

void *valloc (size_t size)

Allocate a block size bytes, starting on a page boundary. See Section 3.3.7 [Aligned Memory Blocks], page 36.

void *memalign (size_t size, size_t boundary)

Allocate a block size bytes, starting on an address that is a multiple of boundary. See Section 3.3.7 [Aligned Memory Blocks], page 36.

void mcheck (void (*abortfn) (void))

Tell malloc to perform occasional consistency checks on dynamically allocated memory, and to call *abortfn* when an inconsistency is found. See Section 3.3.8 [Heap Consistency Checking], page 36.

void *(*__malloc_hook) (size_t size)

A pointer to a function that malloc uses whenever it is called.

void *(*__realloc_hook) (void *ptr, size_t size)

A pointer to a function that realloc uses whenever it is called.

void (*__free_hook) (void *ptr)

A pointer to a function that free uses whenever it is called.

void struct mstats mstats (void)

Read information about the current dynamic memory usage. See Section 3.3.10 [Statistics of Malloc], page 39.

3.4 Obstacks

An obstack is a pool of memory containing a stack of objects. You can create any number of separate obstacks, and then allocate objects in specified obstacks. Within each obstack, the last object allocated must always be the first one freed, but distinct obstacks are independent of each other.

Aside from this one constraint of order of freeing, obstacks are totally general: an obstack can contain any number of objects of any size. They are implemented with macros, so allocation is usually very fast as long as the objects are usually small. And the only space overhead per object is the padding needed to start each object on a suitable boundary.

3.4.1 Creating Obstacks

The utilities for manipulating obstacks are declared in the header file 'obstack.h'.

struct obstack Data Type

An obstack is represented by a data structure of type struct obstack. This structure has a small fixed size; it records the status of the obstack and how to find the space in which objects are allocated. It does not contain any of the objects themselves. You should not try to access the contents of the structure directly; use only the functions described in this chapter.

You can declare variables of type struct obstack and use them as obstacks, or you can allocate obstacks dynamically like any other kind of object. Dynamic allocation of obstacks allows your program to have a variable number of different stacks. (You can even allocate an obstack structure in another obstack, but this is rarely useful.)

All the functions that work with obstacks require you to specify which obstack to use. You do this with a pointer of type struct obstack *. In the following, we often say "an obstack" when strictly speaking the object at hand is such a pointer.

The objects in the obstack are packed into large blocks called *chunks*. The struct obstack structure points to a chain of the chunks currently in use.

The obstack library obtains a new chunk whenever you allocate an object that won't fit in the previous chunk. Since the obstack library manages chunks automatically, you don't need to pay much attention to them, but you do need to supply a function which the obstack library should use to get a chunk. Usually you supply a function which uses malloc directly or indirectly. You must also supply a function to free a chunk. These matters are described in the following section.

3.4.2 Preparing for Using Obstacks

Each source file in which you plan to use the obstack functions must include the header file 'obstack.h', like this:

```
#include <obstack.h>
```

Also, if the source file uses the macro obstack_init, it must declare or define two functions or macros that will be called by the obstack library. One, obstack_chunk_alloc, is used to allocate the chunks of memory into which objects are packed. The other, obstack_chunk_free, is used to return chunks when the objects in them are freed.

Usually these are defined to use malloc via the intermediary xmalloc (see Section 3.3 [Unconstrained Allocation], page 30). This is done with the following pair of macro definitions:

```
#define obstack_chunk_alloc xmalloc
#define obstack_chunk_free free
```

Though the storage you get using obstacks really comes from malloc, using obstacks is faster because malloc is called less often, for larger blocks of memory. See Section 3.4.10 [Obstack Chunks], page 51, for full details.

At run time, before the program can use a struct obstack object as an obstack, it must initialize the obstack by calling obstack_init.

```
\verb|void obstack_init| (\verb|struct obstack| *| obstack| ptr|)
```

Function

Initialize obstack obstack_ptr for allocation of objects.

Here are two examples of how to allocate the space for an obstack and initialize it. First, an obstack that is a static variable:

```
struct obstack myobstack;
...
obstack_init (&myobstack);
```

Second, an obstack that is itself dynamically allocated:

3.4.3 Allocation in an Obstack

The most direct way to allocate an object in an obstack is with obstack_alloc, which is invoked almost like malloc.

```
void * obstack_alloc (struct obstack *obstack ptr, size_t size)

This allocates an uninitialized block of size bytes in an obstack and returns its address.

Here obstack_ptr specifies which obstack to allocate the block in; it is the address of the struct obstack object which represents the obstack. Each obstack function or macro requires you to specify an obstack_ptr as the first argument.
```

For example, here is a function that allocates a copy of a string str in a specific obstack, which is the variable $string_obstack$:

To allocate a block with specified contents, use the function obstack_copy, declared like this:

This allocates a block and initializes it by copying size bytes of data starting at address.

Like obstack_copy, but appends an extra byte containing a null character. This extra byte is not counted in the argument size.

The obstack_copy0 function is convenient for copying a sequence of characters into an obstack as a null-terminated string. Here is an example of its use:

```
char *
obstack_savestring (char *addr, size_t size)
{
   return obstack_copy0 (&myobstack, addr, size);
}
```

Contrast this with the previous example of savestring using malloc (see Section 3.3.1 [Basic Allocation], page 31).

3.4.4 Freeing Objects in an Obstack

To free an object allocated in an obstack, use the function obstack_free. Since the obstack is a stack of objects, freeing one object automatically frees all other objects allocated more recently in the same obstack.

```
void obstack_free (struct obstack *obstack ptr, void *object) Function If object is a null pointer, everything allocated in the obstack is freed. Otherwise, object must be the address of an object allocated in the obstack. Then object is freed, along with everything allocated in obstack since object.
```

Note that if *object* is a null pointer, the result is an uninitialized obstack. To free all storage in an obstack but leave it valid for further allocation, call <code>obstack_free</code> with the address of the first object allocated on the obstack:

```
obstack_free (obstack_ptr, first_object_allocated_ptr);
```

Recall that the objects in an obstack are grouped into chunks. When all the objects in a chunk become free, the obstack library automatically frees the chunk (see Section 3.4.2 [Preparing for Obstacks], page 42). Then other obstacks, or non-obstack allocation, can reuse the space of the chunk.

3.4.5 Obstack Functions and Macros

The interfaces for using obstacks may be defined either as functions or as macros, depending on the compiler. The obstack facility works with all C compilers, including both ANSI C and traditional C, but there are precautions you must take if you plan to use compilers other than GNU C.

If you are using an old-fashioned non-ANSI C compiler, all the obstack "functions" are actually defined only as macros. You can call these macros like functions, but you cannot use them in any other way (for example, you cannot take their address).

Calling the macros requires a special precaution: namely, the first operand (the obstack pointer) may not contain any side effects, because it may be computed more than once. For example, if you write this:

```
obstack_alloc (get_obstack (), 4);
```

you will find that get_obstack may be called several times. If you use *obstack_list_ptr++ as the obstack pointer argument, you will get very strange results since the incrementation may occur several times.

In ANSI C, each function has both a macro definition and a function definition. The function definition is used if you take the address of the function without calling it. An ordinary call uses the macro definition by default, but you can request the function definition instead by writing the function name in parentheses, as shown here:

```
char *x;
void *(*funcp) ();
/* Use the macro. */
x = (char *) obstack_alloc (obptr, size);
/* Call the function. */
x = (char *) (obstack_alloc) (obptr, size);
/* Take the address of the function. */
```

funcp = obstack_alloc;

This is the same situation that exists in ANSI C for the standard library functions. See Section 1.3.2 [Macro Definitions], page 6.

Warning: When you do use the macros, you must observe the precaution of avoiding side effects in the first operand, even in ANSI C.

If you use the GNU C compiler, this precaution is not necessary, because various language extensions in GNU C permit defining the macros so as to compute each argument only once.

3.4.6 Growing Objects

Because storage in obstack chunks is used sequentially, it is possible to build up an object step by step, adding one or more bytes at a time to the end of the object. With this technique, you do not need to know how much data you will put in the object until you come to the end of it. We call this the technique of *growing objects*. The special functions for adding data to the growing object are described in this section.

You don't need to do anything special when you start to grow an object. Using one of the functions to add data to the object automatically starts it. However, it is necessary to say explicitly when the object is finished. This is done with the function obstack_finish.

The actual address of the object thus built up is not known until the object is finished. Until then, it always remains possible that you will add so much data that the object must be copied into a new chunk.

While the obstack is in use for a growing object, you cannot use it for ordinary allocation of another object. If you try to do so, the space already added to the growing object will become part of the other object.

void obstack_blank (struct obstack *obstack ptr, size_t size) Function

The most basic function for adding to a growing object is obstack_blank, which adds

space without initializing it.

To add a block of initialized space, use obstack_grow, which is the growing-object analogue of obstack_copy. It adds size bytes of data to the growing object, copying the contents from data.

This is the growing-object analogue of obstack_copy0. It adds size bytes copied from data, followed by an additional null character.

void obstack_1grow (struct obstack *obstack ptr, char c) Function

To add one character at a time, use the function obstack_1grow. It adds a single byte
containing c to the growing object.

void * obstack_finish (struct obstack *obstack ptr)

Function

When you are finished growing the object, use the function obstack_finish to close it off and return its final address.

Once you have finished the object, the obstack is available for ordinary allocation or for growing another object.

When you build an object by growing it, you will probably need to know afterward how long it became. You need not keep track of this as you grow the object, because you can find out the length from the obstack just before finishing the object with the function obstack_object_size, declared as follows:

size_t obstack_object_size (struct obstack *obstack ptr)

Function

This function returns the current size of the growing object, in bytes. Remember to call this function before finishing the object. After it is finished, obstack_object_size will return zero.

If you have started growing an object and wish to cancel it, you should finish it and then free it, like this:

obstack_free (obstack_ptr, obstack_finish (obstack_ptr));

This has no effect if no object was growing.

You can use obstack_blank with a negative size argument to make the current object smaller. Just don't try to shrink it beyond zero length—there's no telling what will happen if you do that.

3.4.7 Extra Fast Growing Objects

The usual functions for growing objects incur overhead for checking whether there is room for the new growth in the current chunk. If you are frequently constructing objects in small steps of growth, this overhead can be significant.

You can reduce the overhead by using special "fast growth" functions that grow the object without checking. In order to have a robust program, you must do the checking yourself. If you do this checking in the simplest way each time you are about to add data to the object, you have not saved anything, because that is what the ordinary growth functions do. But if you can arrange to check less often, or check more efficiently, then you make the program faster.

The function obstack_room returns the amount of room available in the current chunk. It is declared as follows:

size_t obstack_room (struct obstack *obstack ptr)

Function

This returns the number of bytes that can be added safely to the current growing object (or to an object about to be started) in obstack obstack using the fast growth functions.

While you know there is room, you can use these fast growth functions for adding data to a growing object:

void obstack_1grow_fast (struct obstack *obstack ptr, char c)

Function

The function obstack_1grow_fast adds one byte containing the character c to the growing object in obstack_ptr.

void obstack_blank_fast (struct obstack *obstack ptr, size_t size)

Function

The function obstack_blank_fast adds size bytes to the growing object in obstack obstack_ptr without initializing them.

When you check for space using obstack_room and there is not enough room for what you want to add, the fast growth functions are not safe. In this case, simply use the corresponding ordinary growth function instead. Very soon this will copy the object to a new chunk; then there will be lots of room available again.

So, each time you use an ordinary growth function, check afterward for sufficient space using obstack_room. Once the object is copied to a new chunk, there will be plenty of space again, so the program will start using the fast growth functions again.

Here is an example:

```
void
add_string (struct obstack *obstack, char *ptr, size_t len)
{
  while (len > 0)
    {
      if (obstack_room (obstack) > len)
        {
          /* We have enough room: add everything fast. */
          while (len-- > 0)
            obstack_1grow_fast (obstack, *ptr++);
        }
      else
        {
          /* Not enough room. Add one character slowly,
              which may copy to a new chunk and make room. */
          obstack_1grow (obstack, *ptr++);
          len--;
        }
    }
}
```

3.4.8 Status of an Obstack

Here are functions that provide information on the current status of allocation in an obstack. You can use them to learn about an object while still growing it.

void * obstack_base (struct obstack *obstack ptr)

Function

This function returns the tentative address of the beginning of the currently growing object in obstack_ptr. If you finish the object immediately, it will have that address. If you make it larger first, it may outgrow the current chunk—then its address will change!

If no object is growing, this value says where the next object you allocate will start (once again assuming it fits in the current chunk).

void * obstack_next_free (struct obstack *obstack ptr)

Function

This function returns the address of the first free byte in the current chunk of obstack obstack_ptr. This is the end of the currently growing object. If no object is growing, obstack_next_free returns the same value as obstack_base.

size_t obstack_object_size (struct obstack *obstack ptr)

Function

This function returns the size in bytes of the currently growing object. This is equivalent to

obstack_next_free (obstack_ptr) - obstack_base (obstack_ptr)

3.4.9 Alignment of Data in Obstacks

Each obstack has an alignment boundary; each object allocated in the obstack automatically starts on an address that is a multiple of the specified boundary. By default, this boundary is 4 bytes.

To access an obstack's alignment boundary, use the macro obstack_alignment_mask, whose function prototype looks like this:

int obstack_alignment_mask (struct obstack *obstack ptr)

Macro

The value is a bit mask; a bit that is 1 indicates that the corresponding bit in the address of an object should be 0. The mask value should be one less than a power of 2; the effect is that all object addresses are multiples of that power of 2. The default value of the mask is 3, so that addresses are multiples of 4. A mask value of 0 means an object can start on any multiple of 1 (that is, no alignment is required).

The expansion of the macro obstack_alignment_mask is an lvalue, so you can alter the mask by assignment. For example, this statement:

```
obstack_alignment_mask (obstack_ptr) = 0;
```

has the effect of turning off alignment processing in the specified obstack.

Note that a change in alignment mask does not take effect until after the next time an object is allocated or finished in the obstack. If you are not growing an object, you can make the new alignment mask take effect immediately by calling obstack_finish. This will finish a zero-length object and then do proper alignment for the next object.

3.4.10 Obstack Chunks

Obstacks work by allocating space for themselves in large chunks, and then parceling out space in the chunks to satisfy your requests. Chunks are normally 4096 bytes long unless you specify a different chunk size. The chunk size includes 8 bytes of overhead that are not actually used for storing objects. Regardless of the specified size, longer chunks will be allocated when necessary for long objects.

The obstack library allocates chunks by calling the function obstack_chunk_alloc, which you must define. When a chunk is no longer needed because you have freed all the objects in it, the obstack library frees the chunk by calling obstack_chunk_free, which you must also define.

These two must be defined (as macros) or declared (as functions) in each source file that uses obstack_init (see Section 3.4.1 [Creating Obstacks], page 41). Most often they are defined as macros like this:

```
#define obstack_chunk_alloc xmalloc
#define obstack_chunk_free free
```

Note that these are simple macros (no arguments). Macro definitions with arguments will not work! It is necessary that obstack_chunk_alloc or obstack_chunk_free, alone, expand into a function name if it is not itself a function name.

The function that actually implements obstack_chunk_alloc cannot return "failure" in any fashion, because the obstack library is not prepared to handle failure. Therefore, malloc itself is not suitable. If the function cannot obtain space, it should either terminate the process (see Section 22.3 [Program Termination], page 476) or do a nonlocal exit using longjmp (see Chapter 20 [Non-Local Exits], page 397).

If you allocate chunks with malloc, the chunk size should be a power of 2. The default chunk size, 4096, was chosen because it is long enough to satisfy many typical requests on the obstack yet short enough not to waste too much memory in the portion of the last chunk not yet used.

```
size_t obstack_chunk_size (struct obstack *obstack ptr)
```

Macro

This returns the chunk size of the given obstack.

Since this macro expands to an Ivalue, you can specify a new chunk size by assigning it a new value. Doing so does not affect the chunks already allocated, but will change the size of chunks allocated for that particular obstack in the future. It is unlikely to be useful to make the chunk size smaller, but making it larger might improve efficiency if you are allocating many objects whose size is comparable to the chunk size. Here is how to do so cleanly:

```
if (obstack_chunk_size (obstack_ptr) < new_chunk_size)
  obstack_chunk_size (obstack_ptr) = new_chunk_size;</pre>
```

3.4.11 Summary of Obstack Functions

Here is a summary of all the functions associated with obstacks. Each takes the address of an obstack (struct obstack *) as its first argument.

```
void obstack_init (struct obstack *obstack ptr)
```

Initialize use of an obstack. See Section 3.4.1 [Creating Obstacks], page 41.

void *obstack_alloc (struct obstack *obstack ptr, size_t size)

Allocate an object of *size* uninitialized bytes. See Section 3.4.3 [Allocation in an Obstack], page 43.

```
void *obstack_copy (struct obstack *obstack ptr, void *address, size_t size)
```

Allocate an object of size bytes, with contents copied from address. See Section 3.4.3 [Allocation in an Obstack], page 43.

void *obstack_copy0 (struct obstack *obstack ptr, void *address, size_t size)

Allocate an object of size+1 bytes, with size of them copied from address, followed by a null character at the end. See Section 3.4.3 [Allocation in an Obstack], page 43.

void obstack_free (struct obstack *obstack ptr, void *object)

Free object (and everything allocated in the specified obstack more recently than object). See Section 3.4.4 [Freeing Obstack Objects], page 44.

void obstack_blank (struct obstack *obstack ptr, size_t size)

Add size uninitialized bytes to a growing object. See Section 3.4.6 [Growing Objects], page 46.

void obstack_grow (struct obstack *obstack ptr, void *address, size_t size)

Add size bytes, copied from address, to a growing object. See Section 3.4.6 [Growing Objects], page 46.

void obstack_grow0 (struct obstack *obstack ptr, void *address, size_t size)

Add size bytes, copied from address, to a growing object, and then add another byte containing a null character. See Section 3.4.6 [Growing Objects], page 46.

void obstack_1grow (struct obstack *obstack ptr, char data char)

Add one byte containing data_char to a growing object. See Section 3.4.6 [Growing Objects], page 46.

void *obstack_finish (struct obstack *obstack ptr)

Finalize the object that is growing and return its permanent address. See Section 3.4.6 [Growing Objects], page 46.

size_t obstack_object_size (struct obstack *obstack ptr)

Get the current size of the currently growing object. See Section 3.4.6 [Growing Objects], page 46.

void obstack_blank_fast (struct obstack *obstack ptr, size_t size)

Add size uninitialized bytes to a growing object without checking that there is enough room. See Section 3.4.7 [Extra Fast Growing], page 48.

void obstack_1grow_fast (struct obstack *obstack ptr, char data char)

Add one byte containing data_char to a growing object without checking that there is enough room. See Section 3.4.7 [Extra Fast Growing], page 48.

size_t obstack_room (struct obstack *obstack ptr)

Get the amount of room now available for growing the current object. See Section 3.4.7 [Extra Fast Growing], page 48.

int obstack_alignment_mask (struct obstack *obstack ptr)

The mask used for aligning the beginning of an object. This is an Ivalue. See Section 3.4.9 [Obstacks Data Alignment], page 50.

size_t obstack_chunk_size (struct obstack *obstack ptr)

The size for allocating chunks. This is an Ivalue. See Section 3.4.10 [Obstack Chunks], page 51.

void *obstack_base (struct obstack *obstack ptr)

54

Tentative starting address of the currently growing object. See Section 3.4.8 [Status of an Obstack], page 49.

void *obstack_next_free (struct obstack *obstack ptr)

Address just after the end of the currently growing object. See Section 3.4.8 [Status of an Obstack], page 49.

3.5 Automatic Storage with Variable Size

The function alloca supports a kind of half-dynamic allocation in which blocks are allocated dynamically but freed automatically.

Allocating a block with alloca is an explicit action; you can allocate as many blocks as you wish, and compute the size at run time. But all the blocks are freed when you exit the function that alloca was called from, just as if they were automatic variables declared in that function. There is no way to free the space explicitly.

The prototype for alloca is in 'stdlib.h'. This function is a BSD extension.

void * alloca (size_t size);

Function

The return value of alloca is the address of a block of size bytes of storage, allocated in the stack frame of the calling function.

Do not use alloca inside the arguments of a function call—you will get unpredictable results, because the stack space for the alloca would appear on the stack in the middle of the space for the function arguments. An example of what to avoid is foo (x, alloca (4), y).

3.5.1 alloca Example

As an example of use of alloca, here is a function that opens a file name made from concatenating two argument strings, and returns a file descriptor or minus one signifying failure:

```
int
open2 (char *str1, char *str2, int flags, int mode)
{
   char *name = (char *) alloca (strlen (str1) + strlen (str2) + 1);
   strcpy (name, str1);
   strcat (name, str2);
   return open (name, flags, mode);
}
```

Here is how you would get the same results with malloc and free:

```
int
open2 (char *str1, char *str2, int flags, int mode)
{
   char *name = (char *) malloc (strlen (str1) + strlen (str2) + 1);
   int desc;
   if (name == 0)
     fatal ("virtual memory exceeded");
   strcpy (name, str1);
   strcat (name, str2);
   desc = open (name, flags, mode);
   free (name);
   return desc;
}
```

As you can see, it is simpler with alloca. But alloca has other, more important advantages, and some disadvantages.

3.5.2 Advantages of alloca

Here are the reasons why alloca may be preferable to malloc:

- Using alloca wastes very little space and is very fast. (It is open-coded by the GNU C compiler.)
- Since alloca does not have separate pools for different sizes of block, space used for any size block can be reused for any other size. alloca does not cause storage fragmentation.
- Nonlocal exits done with longjmp (see Chapter 20 [Non-Local Exits], page 397) automatically free the space allocated with alloca when they exit through the function that called alloca. This is the most important reason to use alloca.

To illustrate this, suppose you have a function open_or_report_error which returns a descriptor, like open, if it succeeds, but does not return to its caller if it fails. If the file cannot be opened, it prints an error message and jumps out to the command level of your program using longjmp. Let's change open2 (see Section 3.5.1 [Alloca Example], page 54) to use this subroutine:

```
int
open2 (char *str1, char *str2, int flags, int mode)
{
   char *name = (char *) alloca (strlen (str1) + strlen (str2) + 1);
   strcpy (name, str1);
   strcat (name, str2);
   return open_or_report_error (name, flags, mode);
}
```

Because of the way alloca works, the storage it allocates is freed even when an error occurs, with no special effort required.

By contrast, the previous definition of open2 (which uses malloc and free) would develop a storage leak if it were changed in this way. Even if you are willing to make more changes to fix it, there is no easy way to do so.

3.5.3 Disadvantages of alloca

These are the disadvantages of alloca in comparison with malloc:

- If you try to allocate more storage than the machine can provide, you don't get a clean error message. Instead you get a fatal signal like the one you would get from an infinite recursion; probably a segmentation violation (see Section 21.2.1 [Program Error Signals], page 406).
- Some non-GNU systems fail to support alloca, so it is less portable. However, a slower emulation of alloca written in C is available for use on systems with this deficiency.

3.5.4 GNU C Variable-Size Arrays

In GNU C, you can replace most uses of alloca with an array of variable size. Here is how open2 would look then:

```
int open2 (char *str1, char *str2, int flags, int mode)
```

```
{
  char name[strlen (str1) + strlen (str2) + 1];
  strcpy (name, str1);
  strcat (name, str2);
  return open (name, flags, mode);
}
```

But alloca is not always equivalent to a variable-sized array, for several reasons:

- A variable size array's space is freed at the end of the scope of the name of the array. The space allocated with alloca usually remains until the end of the function.
- It is possible to use alloca within a loop, allocating an additional block on each iteration. This is impossible with variable-sized arrays. On the other hand, this is also slightly unclean.

Note: If you mix use of alloca and variable-sized arrays within one function, exiting a scope in which a variable-sized array was declared frees all blocks allocated with alloca during the execution of that scope.

3.6 Relocating Allocator

Any system of dynamic memory allocation has overhead: the amount of space it uses is more than the amount the program asks for. The *relocating memory allocator* achieves very low overhead by moving blocks in memory as necessary, on its own initiative.

3.6.1 Concepts of Relocating Allocation

When you allocate a block with malloc, the address of the block never changes unless you use realloc to change its size. Thus, you can safely store the address in various places, temporarily or permanently, as you like. This is not safe when you use the relocating memory allocator, because any and all relocatable blocks can move whenever you allocate memory in any fashion. Even calling malloc or realloc can move the relocatable blocks.

For each relocatable block, you must make a handle—a pointer object in memory, designated to store the address of that block. The relocating allocator knows where each block's handle is, and updates the address stored there whenever it moves the block, so that the handle always points to

the block. Each time you access the contents of the block, you should fetch its address anew from the handle.

To call any of the relocating allocator functions from a signal handler is almost certainly incorrect, because the signal could happen at any time and relocate all the blocks. The only way to make this safe is to block the signal around any access to the contents of any relocatable block—not a convenient mode of operation. See Section 21.4.6 [Nonreentrancy], page 434.

3.6.2 Allocating and Freeing Relocatable Blocks

In the descriptions below, handleptr designates the address of the handle. All the functions are declared in 'malloc.h'; all are GNU extensions.

void * r_alloc (void **handleptr, size_t size)

Function

This function allocates a relocatable block of size size. It stores the block's address in *handleptr and returns a non-null pointer to indicate success.

If r_alloc can't get the space needed, it stores a null pointer in *handleptr, and returns a null pointer.

void r_alloc_free (void **handleptr)

Function

This function is the way to free a relocatable block. It frees the block that *handleptr points to, and stores a null pointer in *handleptr to show it doesn't point to an allocated block any more.

void * r_re_alloc (void **handleptr, size_t size)

Function

The function r_re_alloc adjusts the size of the block that *handleptr points to, making it size bytes long. It stores the address of the resized block in *handleptr and returns a non-null pointer to indicate success.

If enough memory is not available, this function returns a null pointer and does not modify *handleptr.

3.7 Memory Usage Warnings

You can ask for warnings as the program approaches running out of memory space, by calling memory_warnings. This is a GNU extension declared in 'malloc.h'.

void memory_warnings (void *start, void (*warn func) (char *)) Function Call this function to request warnings for nearing exhaustion of virtual memory.

The argument start says where data space begins, in memory. The allocator compares this against the last address used and against the limit of data space, to determine the fraction of available memory in use. If you supply zero for start, then a default value is used which is right in most circumstances.

For warn_func, supply a function that malloc can call to warn you. It is called with a string (a warning message) as argument. Normally it ought to display the string for the user to read.

The warnings come when memory becomes 75% full, when it becomes 85% full, and when it becomes 95% full. Above 95% you get another warning each time memory usage increases.

60

4 Character Handling

Programs that work with characters and strings often need to classify a character—is it alphabetic, is it a digit, is it whitespace, and so on—and perform case conversion operations on characters. The functions in the header file 'ctype.h' are provided for this purpose.

Since the choice of locale and character set can alter the classifications of particular character codes, all of these functions are affected by the current locale. (More precisely, they are affected by the locale currently selected for character classification—the LC_CTYPE category; see Section 7.3 [Locale Categories], page 98.)

4.1 Classification of Characters

This section explains the library functions for classifying characters. For example, **isalpha** is the function to test for an alphabetic character. It takes one argument, the character to test, and returns a nonzero integer if the character is alphabetic, and zero otherwise. You would use it like this:

```
if (isalpha (c))
  printf ("The character '%c' is alphabetic.\n", c);
```

Each of the functions in this section tests for membership in a particular class of characters; each has a name starting with 'is'. Each of them takes one argument, which is a character to test, and returns an int which is treated as a boolean value. The character argument is passed as an int, and it may be the constant value EOF instead of a real character.

The attributes of any given character can vary between locales. See Chapter 7 [Locales], page 97, for more information on locales.

These functions are declared in the header file 'ctype.h'.

```
int islower (int c)
```

Function

Returns true if c is a lower-case letter.

int isupper (int c)

Function

Returns true if c is an upper-case letter.

int isalpha (int c)

Function

Returns true if c is an alphabetic character (a letter). If islower or isupper is true of a character, then isalpha is also true.

In some locales, there may be additional characters for which isalpha is true—letters which are neither upper case nor lower case. But in the standard "C" locale, there are no such additional characters.

int isdigit (int c)

Function

Returns true if c is a decimal digit ('0' through '9').

int isalnum (int c)

Function

Returns true if c is an alphanumeric character (a letter or number); in other words, if either isalpha or isdigit is true of a character, then isalnum is also true.

int isxdigit (int c)

Function

Returns true if c is a hexadecimal digit. Hexadecimal digits include the normal decimal digits '0' through '9' and the letters 'A' through 'F' and 'a' through 'f'.

int ispunct (int c)

Function

Returns true if c is a punctuation character. This means any printing character that is not alphanumeric or a space character.

int isspace (int c)

Function

Returns true if c is a whitespace character. In the standard "C" locale, isspace returns true for only the standard whitespace characters:

- , , space
- '\f' formfeed
- '\n' newline
- '\r' carriage return

'\t' horizontal tab

'\v' vertical tab

int isblank (int c)

Function

Returns true if c is a blank character; that is, a space or a tab. This function is a GNU extension.

int isgraph (int c)

Function

Returns true if c is a graphic character; that is, a character that has a glyph associated with it. The whitespace characters are not considered graphic.

int isprint (int c)

Function

Returns true if c is a printing character. Printing characters include all the graphic characters, plus the space ('') character.

int iscntrl (int c)

Function

Returns true if c is a control character (that is, a character that is not a printing character).

int isascii (int c)

Function

Returns true if c is a 7-bit unsigned char value that fits into the US/UK ASCII character set. This function is a BSD extension and is also an SVID extension.

4.2 Case Conversion

This section explains the library functions for performing conversions such as case mappings on characters. For example, toupper converts any character to upper case if possible. If the character can't be converted, toupper returns it unchanged.

These functions take one argument of type int, which is the character to convert, and return the converted character as an int. If the conversion is not applicable to the argument given, the argument is returned unchanged.

The GNU C Library

Compatibility Note: In pre-ANSI C dialects, instead of returning the argument unchanged, these functions may fail when the argument is not suitable for the conversion. Thus for portability, you may need to write islower(c)? toupper(c): c rather than just toupper(c).

These functions are declared in the header file 'ctype.h'.

int tolower (int c)

64

Function

If c is an upper-case letter, tolower returns the corresponding lower-case letter. If c is not an upper-case letter, c is returned unchanged.

int toupper (int c)

Function

If c is a lower-case letter, tolower returns the corresponding upper-case letter. Otherwise c is returned unchanged.

int toascii (int c)

Function

This function converts c to a 7-bit unsigned char value that fits into the US/UK ASCII character set, by clearing the high-order bits. This function is a BSD extension and is also an SVID extension.

int _tolower (int c)

Function

This is identical to tolower, and is provided for compatibility with the SVID. See Section 1.2.4 [SVID], page 4.

int _toupper (int c)

Function

This is identical to toupper, and is provided for compatibility with the SVID.

5 String and Array Utilities

Operations on strings (or arrays of characters) are an important part of many programs. The GNU C library provides an extensive set of string utility functions, including functions for copying, concatenating, comparing, and searching strings. Many of these functions can also operate on arbitrary regions of storage; for example, the memcpy function can be used to copy the contents of any kind of array.

It's fairly common for beginning C programmers to "reinvent the wheel" by duplicating this functionality in their own code, but it pays to become familiar with the library functions and to make use of them, since this offers benefits in maintenance, efficiency, and portability.

For instance, you could easily compare one string to another in two lines of C code, but if you use the built-in **strcmp** function, you're less likely to make a mistake. And, since these library functions are typically highly optimized, your program may run faster too.

5.1 Representation of Strings

This section is a quick summary of string concepts for beginning C programmers. It describes how character strings are represented in C and some common pitfalls. If you are already familiar with this material, you can skip this section.

A string is an array of char objects. But string-valued variables are usually declared to be pointers of type char *. Such variables do not include space for the text of a string; that has to be stored somewhere else—in an array variable, a string constant, or dynamically allocated memory (see Chapter 3 [Memory Allocation], page 29). It's up to you to store the address of the chosen memory space into the pointer variable. Alternatively you can store a null pointer in the pointer variable. The null pointer does not point anywhere, so attempting to reference the string it points to gets an error.

By convention, a *null character*, '\0', marks the end of a string. For example, in testing to see whether the char * variable p points to a null character marking the end of a string, you can write !*p or $*p == '\0'$.

A null character is quite different conceptually from a null pointer, although both are represented by the integer 0.

String literals appear in C program source as strings of characters between double-quote characters (""). In ANSI C, string literals can also be formed by string concatenation: "a" "b" is the same as "ab". Modification of string literals is not allowed by the GNU C compiler, because literals are placed in read-only storage.

Character arrays that are declared const cannot be modified either. It's generally good style to declare non-modifiable string pointers to be of type const char *, since this often allows the C compiler to detect accidental modifications as well as providing some amount of documentation about what your program intends to do with the string.

The amount of memory allocated for the character array may extend past the null character that normally marks the end of the string. In this document, the term allocation size is always used to refer to the total amount of memory allocated for the string, while the term length refers to the number of characters up to (but not including) the terminating null character.

A notorious source of program bugs is trying to put more characters in a string than fit in its allocated size. When writing code that extends strings or moves characters into a pre-allocated array, you should be very careful to keep track of the length of the text and make explicit checks for overflowing the array. Many of the library functions do not do this for you! Remember also that you need to allocate an extra byte to hold the null character that marks the end of the string.

5.2 String/Array Conventions

This chapter describes both functions that work on arbitrary arrays or blocks of memory, and functions that are specific to null-terminated arrays of characters.

Functions that operate on arbitrary blocks of memory have names beginning with 'mem' (such as memcpy) and invariably take an argument which specifies the size (in bytes) of the block of memory to operate on. The array arguments and return values for these functions have type void *, and as a matter of style, the elements of these arrays are referred to as "bytes". You can pass any kind of pointer to these functions, and the sizeof operator is useful in computing the value for the size argument.

In contrast, functions that operate specifically on strings have names beginning with 'str' (such as strcpy) and look for a null character to terminate the string instead of requiring an explicit size argument to be passed. (Some of these functions accept a specified maximum length, but they also check for premature termination with a null character.) The array arguments and return values for these functions have type char *, and the array elements are referred to as "characters".

In many cases, there are both 'mem' and 'str' versions of a function. The one that is more appropriate to use depends on the exact situation. When your program is manipulating arbitrary arrays or blocks of storage, then you should always use the 'mem' functions. On the other hand, when you are manipulating null-terminated strings it is usually more convenient to use the 'str' functions, unless you already know the length of the string in advance.

5.3 String Length

You can get the length of a string using the **strlen** function. This function is declared in the header file 'string.h'.

```
size_t strlen (const char *s)
```

Function

The strlen function returns the length of the null-terminated string s. (In other words, it returns the offset of the terminating null character within the array.)

For example,

```
strlen ("hello, world") \Rightarrow 12
```

When applied to a character array, the strlen function returns the length of the string stored there, not its allocation size. You can get the allocation size of the character array that holds a string using the sizeof operator:

```
char string[32] = "hello, world";
sizeof (string)
     ⇒ 32
strlen (string)
     ⇒ 12
```

5.4 Copying and Concatenation

You can use the functions described in this section to copy the contents of strings and arrays, or to append the contents of one string to another. These functions are declared in the header file 'string.h'.

A helpful way to remember the ordering of the arguments to the functions in this section is that it corresponds to an assignment expression, with the destination array specified to the left of the source array. All of these functions return the address of the destination array.

Most of these functions do not work properly if the source and destination arrays overlap. For example, if the beginning of the destination array overlaps the end of the source array, the original contents of that part of the source array may get overwritten before it is copied. Even worse, in the case of the string functions, the null character marking the end of the string may be lost, and the copy function might get stuck in a loop trashing all the memory allocated to your program.

All functions that have problems copying between overlapping arrays are explicitly identified in this manual. In addition to functions in this section, there are a few others like **sprintf** (see Section 11.9.7 [Formatted Output Functions], page 159) and **scanf** (see Section 11.11.8 [Formatted Input Functions], page 181).

```
void * memcpy (void *to, const void *from, size_t size)
```

Function

The memcpy function copies size bytes from the object beginning at from into the object beginning at to. The behavior of this function is undefined if the two arrays to and from overlap; use memmove instead if overlapping is possible.

The value returned by memcpy is the value of to.

Here is an example of how you might use memcpy to copy the contents of a struct:

```
struct foo *old, *new;
...
memcpy (new, old, sizeof(struct foo));
```

```
void * memmove (void *to, const void *from, size_t size)
```

Function

memmove copies the size bytes at from into the size bytes at to, even if those two blocks of space overlap. In the case of overlap, memmove is careful to copy the original values of the bytes in the block at from, including those bytes which also belong to the block at to.

```
void * memccpy (void *to, const void *from, int c, size_t size)
```

Function

This function copies no more than size bytes from from to to, stopping if a byte matching c is found. The return value is a pointer into to one byte past where c was copied, or a null pointer if no byte matching c appeared in the first size bytes of from.

void * memset (void *block, int c, size_t size)

Function

This function copies the value of c (converted to an unsigned char) into each of the first size bytes of the object beginning at block. It returns the value of block.

char * strcpy (char *to, const char *from)

Function

This copies characters from the string from (up to and including the terminating null character) into the string to. Like memcpy, this function has undefined results if the strings overlap. The return value is the value of to.

char * strncpy (char *to, const char *from, size_t size)

Function

This function is similar to strcpy but always copies exactly size characters into to.

If the length of from is more than size, then strncpy copies just the first size characters.

If the length of from is less than size, then strncpy copies all of from, followed by enough null characters to add up to size characters in all. This behavior is rarely useful, but it is specified by the ANSI C standard.

The behavior of **strncpy** is undefined if the strings overlap.

Using strncpy as opposed to strcpy is a way to avoid bugs relating to writing past the end of the allocated space for to. However, it can also make your program much slower in one common case: copying a string which is probably small into a potentially large buffer. In this case, size may be large, and when it is, strncpy will waste a considerable amount of time copying null characters.

char * strdup (const char *s)

Function

This function copies the null-terminated string s into a newly allocated string. The string is allocated using malloc; see Section 3.3 [Unconstrained Allocation], page 30. If malloc cannot allocate space for the new string, strdup returns a null pointer. Otherwise it returns a pointer to the new string.

char * stpcpy (char *to, const char *from)

Function

This function is like **strcpy**, except that it returns a pointer to the end of the string to (that is, the address of the terminating null character) rather than the beginning.

For example, this program uses stpcpy to concatenate 'foo' and 'bar' to produce 'foobar', which it then prints.

```
#include <string.h>
int
main (void)
{
   char *to = buffer;
   to = stpcpy (to, "foo");
   to = stpcpy (to, "bar");
   printf ("%s\n", buffer);
}
```

This function is not part of the ANSI or POSIX standards, and is not customary on Unix systems, but we did not invent it either. Perhaps it comes from MS-DOG.

Its behavior is undefined if the strings overlap.

```
char * strcat (char *to, const char *from)
```

Function

The strcat function is similar to strcpy, except that the characters from from are concatenated or appended to the end of to, instead of overwriting it. That is, the first character from from overwrites the null character marking the end of to.

An equivalent definition for strcat would be:

```
char *
strcat (char *to, const char *from)
{
   strcpy (to + strlen (to), from);
   return to;
}
```

This function has undefined results if the strings overlap.

```
char * strncat (char *to, const char *from, size_t size)
```

Function

This function is like **strcat** except that not more than *size* characters from *from* are appended to the end of to. A single null character is also always appended to to, so the total allocated size of to must be at least *size* + 1 bytes longer than its initial length.

```
char *
strncat (char *to, const char *from, size_t size)
{
   strncpy (to + strlen (to), from, size);
   return to;
}
```

The behavior of strncat is undefined if the strings overlap.

Here is an example showing the use of strncpy and strncat. Notice how, in the call to strncat, the size parameter is computed to avoid overflowing the character array buffer.

```
#include <string.h>
#include <stdio.h>

#define SIZE 10

static char buffer[SIZE];

main ()
{
    strncpy (buffer, "hello", SIZE);
    printf ("%s\n", buffer);
    strncat (buffer, ", world", SIZE - strlen (buffer) - 1);
    printf ("%s\n", buffer);
}
```

The output produced by this program looks like:

```
hello, wo
```

```
void * bcopy (void *from, const void *to, size_t size)
Function
```

This is a partially obsolete alternative for memmove, derived from BSD. Note that it is not quite equivalent to memmove, because the arguments are not in the same order.

void * bzero (void *block, size_t size)

Function

This is a partially obsolete alternative for memset, derived from BSD. Note that it is not as general as memset, because the only value it can store is zero.

5.5 String/Array Comparison

You can use the functions in this section to perform comparisons on the contents of strings and arrays. As well as checking for equality, these functions can also be used as the ordering functions for sorting operations. See Chapter 8 [Searching and Sorting], page 107, for an example of this.

Unlike most comparison operations in C, the string comparison functions return a nonzero value if the strings are *not* equivalent rather than if they are. The sign of the value indicates the relative ordering of the first characters in the strings that are not equivalent: a negative value indicates that the first string is "less" than the second, while a positive value indicates that the first string is "greater".

If you are using these functions only to check for equality, you might find it makes for a cleaner program to hide them behind a macro definition, like this:

```
#define str_eq(s1,s2) (!strcmp ((s1),(s2)))
```

All of these functions are declared in the header file 'string.h'.

```
int memcmp (const void *a1, const void *a2, size_t size)
```

Function

The function memcmp compares the size bytes of memory beginning at a1 against the size bytes of memory beginning at a2. The value returned has the same sign as the difference between the first differing pair of bytes (interpreted as unsigned char objects, then promoted to int).

If the contents of the two blocks are equal, memcmp returns 0.

On arbitrary arrays, the memcmp function is mostly useful for testing equality. It usually isn't meaningful to do byte-wise ordering comparisons on arrays of things other than bytes. For example, a byte-wise comparison on the bytes that make up floating-point numbers isn't likely to tell you anything about the relationship between the values of the floating-point numbers.

You should also be careful about using memcmp to compare objects that can contain "holes", such as the padding inserted into structure objects to enforce alignment requirements, extra space at the end of unions, and extra characters at the ends of strings whose length is less than their allocated size. The contents of these "holes" are indeterminate and may cause strange behavior when performing byte-wise comparisons. For more predictable results, perform an explicit component-wise comparison.

For example, given a structure type definition like:

you are better off writing a specialized comparison function to compare **struct foo** objects instead of comparing them with memcmp.

```
int stremp (const char *s1, const char *s2)
```

Function

The strcmp function compares the string s1 against s2, returning a value that has the same sign as the difference between the first differing pair of characters (interpreted as unsigned char objects, then promoted to int).

If the two strings are equal, strcmp returns 0.

A consequence of the ordering used by **strcmp** is that if s1 is an initial substring of s2, then s1 is considered to be "less than" s2.

```
int streasecmp (const char *s1, const char *s2)
```

Function

This function is like strcmp, except that differences in case are ignored.

strcasecmp is derived from BSD.

```
int strncasecmp (const char *s1, const char *s2, size_t n)
```

Function

This function is like strncmp, except that differences in case are ignored.

strncasecmp is a GNU extension.

```
int strncmp (const char *s1, const char *s2, size_t size)
```

Function

This function is the similar to strcmp, except that no more than size characters are compared. In other words, if the two strings are the same in their first size characters, the return value is zero.

Here are some examples showing the use of strcmp and strncmp. These examples assume the use of the ASCII character set. (If some other character set—say, EBCDIC—is used instead, then the glyphs are associated with different numeric codes, and the return values and ordering may differ.)

```
int \mathbf{bcmp} (const void *a1, const void *a2, size_t size)
```

Function

This is an obsolete alias for memcmp, derived from BSD.

5.6 Collation Functions

In some locales, the conventions for lexicographic ordering differ from the strict numeric ordering of character codes. For example, in Spanish most glyphs with diacritical marks such as accents are not considered distinct letters for the purposes of collation. On the other hand, the two-character sequence '11' is treated as a single letter that is collated immediately after '1'.

You can use the functions strcoll and strxfrm (declared in the header file 'string.h') to compare strings using a collation ordering appropriate for the current locale. The locale used by these functions in particular can be specified by setting the locale for the LC_COLLATE category; see Chapter 7 [Locales], page 97.

In the standard C locale, the collation sequence for strcoll is the same as that for strcmp.

Effectively, the way these functions work is by applying a mapping to transform the characters in a string to a byte sequence that represents the string's position in the collating sequence of the current locale. Comparing two such byte sequences in a simple fashion is equivalent to comparing the strings with the locale's collating sequence.

The function strcoll performs this translation implicitly, in order to do one comparison. By contrast, strxfrm performs the mapping explicitly. If you are making multiple comparisons using the same string or set of strings, it is likely to be more efficient to use strxfrm to transform all the strings just once, and subsequently compare the transformed strings with strcmp.

```
int strcoll (const char *s1, const char *s2) Function

The strcoll function is similar to strcmp but uses the collating sequence of the current locale for collation (the LC_COLLATE locale).
```

Here is an example of sorting an array of strings, using **strcoll** to compare them. The actual sort algorithm is not written here; it comes from **qsort** (see Section 8.3 [Array Sort Function], page 108). The job of the code shown here is to say how to compare the strings while sorting them. (Later on in this section, we will show a way to do this more efficiently using **strxfrm**.)

```
/* This is the comparison function used with qsort. */
int
compare_elements (char **p1, char **p2)
{
   return strcoll (*p1, *p2);
}

/* This is the entry point—the function to sort
   strings using the locale's collating sequence. */

void
sort_strings (char **array, int nstrings)
```

```
size_t strxfrm (char *to, const char *from, size_t size)
```

Function

The function **strxfrm** transforms *string* using the collation transformation determined by the locale currently selected for collation, and stores the transformed string in the array *to*. Up to *size* characters (including a terminating null character) are stored.

The behavior is undefined if the strings to and from overlap; see Section 5.4 [Copying and Concatenation], page 67.

The return value is the length of the entire transformed string. This value is not affected by the value of *size*, but if it is greater than *size*, it means that the transformed string did not entirely fit in the array to. In this case, only as much of the string as actually fits was stored. To get the whole transformed string, call **strxfrm** again with a bigger output array.

The transformed string may be longer than the original string, and it may also be shorter.

If size is zero, no characters are stored in to. In this case, strxfrm simply returns the number of characters that would be the length of the transformed string. This is useful for determining what size string to allocate. It does not matter what to is if size is zero; to may even be a null pointer.

Here is an example of how you can use **strxfrm** when you plan to do many comparisons. It does the same thing as the previous example, but much faster, because it has to transform each string only once, no matter how many times it is compared with other strings. Even the time needed to allocate and free storage is much less than the time we save, when there are many strings.

```
struct sorter { char *input; char *transformed; };
/* This is the comparison function used with qsort
    to sort an array of struct sorter. */
int
```

```
compare_elements (struct sorter *p1, struct sorter *p2)
 return strcmp (p1->transformed, p2->transformed);
}
/* This is the entry point—the function to sort
   strings using the locale's collating sequence. */
void
sort_strings_fast (char **array, int nstrings)
  struct sorter temp_array[nstrings];
  int i;
  /* Set up temp_array. Each element contains
     one input string and its transformed string. */
  for (i = 0; i < nstrings; i++)
    {
      size_t length = strlen (array[i]) * 2;
      temp_array[i].input = array[i];
      /* Transform array[i].
         First try a buffer probably big enough. */
      while (1)
        {
          char *transformed = (char *) xmalloc (length);
          if (strxfrm (transformed, array[i], length) < length)
               temp_array[i].transformed = transformed;
               break;
          /* Try again with a bigger buffer. */
          free (transformed);
           length *= 2;
    }
  /* Sort temp_array by comparing transformed strings. */
  qsort (temp_array, sizeof (struct sorter),
         nstrings, compare_elements);
  /* Put the elements back in the permanent array
     in their sorted order. */
  for (i = 0; i < nstrings; i++)</pre>
    array[i] = temp_array[i].input;
  /* Free the strings we allocated. */
  for (i = 0; i < nstrings; i++)</pre>
    free (temp_array[i].transformed);
```

}

Compatibility Note: The string collation functions are a new feature of ANSI C. Older C dialects have no equivalent feature.

5.7 Search Functions

This section describes library functions which perform various kinds of searching operations on strings and arrays. These functions are declared in the header file 'string.h'.

```
void * memchr (const void *block, int c, size_t size)
```

Function

This function finds the first occurrence of the byte c (converted to an unsigned char) in the initial size bytes of the object beginning at block. The return value is a pointer to the located byte, or a null pointer if no match was found.

```
char * strchr (const char *string, int c)
```

Function

The **strchr** function finds the first occurrence of the character c (converted to a **char**) in the null-terminated string beginning at *string*. The return value is a pointer to the located character, or a null pointer if no match was found.

For example,

The terminating null character is considered to be part of the string, so you can use this function get a pointer to the end of a string by specifying a null character as the value of the c argument.

```
char * strrchr (const char *string, int c)
```

Function

The function strrchr is like strchr, except that it searches backwards from the end of the string string (instead of forwards from the front).

For example,

```
strrchr ("hello, world", 'l')

⇒ "ld"
```

char * strstr (const char *haystack, const char *needle)

Function

This is like **strchr**, except that it searches *haystack* for a substring *needle* rather than just a single character. It returns a pointer into the string *haystack* that is the first character of the substring, or a null pointer if no match was found. If *needle* is an empty string, the function returns *haystack*.

For example,

Function

This is like strstr, but needle and haystack are byte arrays rather than null-terminated strings. needle_len is the length of needle and haystack_len is the length of haystack.

This function is a GNU extension.

```
size_t strspn (const char *string, const char *skipset)
```

Function

The strspn ("string span") function returns the length of the initial substring of string that consists entirely of characters that are members of the set specified by the string skipset. The order of the characters in skipset is not important.

For example,

```
strspn ("hello, world", "abcdefghijklmnopqrstuvwxyz") \Rightarrow 5
```

```
size_t strcspn (const char *string, const char *stopset)
```

Function

The strcspn ("string complement span") function returns the length of the initial substring of string that consists entirely of characters that are not members of the set specified by the string stopset. (In other words, it returns the offset of the first character in string that is a member of the set stopset.)

For example,

```
char * strpbrk (const char *string, const char *stopset)
```

Function

The strpbrk ("string pointer break") function is related to strcspn, except that it returns a pointer to the first character in *string* that is a member of the set *stopset* instead of the length of the initial substring. It returns a null pointer if no such character from *stopset* is found.

For example,

```
strpbrk ("hello, world", " \t^n,:!?")
\Rightarrow ", world"
```

5.8 Finding Tokens in a String

It's fairly common for programs to have a need to do some simple kinds of lexical analysis and parsing, such as splitting a command string up into tokens. You can do this with the strtok function, declared in the header file 'string.h'.

```
char * strtok (char *newstring, const char *delimiters)
```

Function

A string can be split into tokens by making a series of calls to the function strtok.

The string to be split up is passed as the newstring argument on the first call only. The strtok function uses this to set up some internal state information. Subsequent calls to get additional tokens from the same string are indicated by passing a null pointer as the newstring argument. Calling strtok with another non-null newstring argument

reinitializes the state information. It is guaranteed that no other library function ever calls strtok behind your back (which would mess up this internal state information).

The delimiters argument is a string that specifies a set of delimiters that may surround the token being extracted. All the initial characters that are members of this set are discarded. The first character that is not a member of this set of delimiters marks the beginning of the next token. The end of the token is found by looking for the next character that is a member of the delimiter set. This character in the original string newstring is overwritten by a null character, and the pointer to the beginning of the token in newstring is returned.

On the next call to strtok, the searching begins at the next character beyond the one that marked the end of the previous token. Note that the set of delimiters delimiters do not have to be the same on every call in a series of calls to strtok.

If the end of the string newstring is reached, or if the remainder of string consists only of delimiter characters, strtok returns a null pointer.

Warning: Since strtok alters the string it is parsing, you always copy the string to a temporary buffer before parsing it with strtok. If you allow strtok to modify a string that came from another part of your program, you are asking for trouble; that string may be part of a data structure that could be used for other purposes during the parsing, when alteration by strtok makes the data structure temporarily inaccurate.

The string that you are operating on might even be a constant. Then when **strtok** tries to modify it, your program will get a fatal signal for writing in read-only memory. See Section 21.2.1 [Program Error Signals], page 406.

This is a special case of a general principle: if a part of a program does not have as its purpose the modification of a certain data structure, then it is error-prone to modify the data structure temporarily.

The function strtok is not reentrant. See Section 21.4.6 [Nonreentrancy], page 434, for a discussion of where and why reentrancy is important.

Here is a simple example showing the use of strtok.

```
#include <string.h>
#include <stddef.h>
```

```
. . .
char string[] = "words separated by spaces -- and, punctuation!";
const char delimiters[] = " .,;:!-";
char *token;
token = strtok (string, delimiters); /* token => "words" */
                                     /* token => "separated" */
token = strtok (NULL, delimiters);
                                      /* token => "by" */
token = strtok (NULL, delimiters);
                                     /* token => "spaces" */
token = strtok (NULL, delimiters);
token = strtok (NULL, delimiters);
                                     /* token => "and" */
token = strtok (NULL, delimiters);
                                     /* token => "punctuation" */
token = strtok (NULL, delimiters);
                                     /* token => NULL */
```

6 Extended Characters

A number of languages use character sets that are larger than the range of values of type char. Japanese and Chinese are probably the most familiar examples.

The GNU C library includes support for two mechanisms for dealing with extended character sets: multibyte characters and wide characters. This chapter describes how to use these mechanisms, and the functions for converting between them.

The behavior of the functions in this chapter is affected by the current locale for character classification—the LC_CTYPE category; see Section 7.3 [Locale Categories], page 98. This choice of locale selects which multibyte code is used, and also controls the meanings and characteristics of wide character codes.

6.1 Introduction to Extended Characters

You can represent extended characters in either of two ways:

- As Multibyte characters which can be embedded in an ordinary string, an array of char objects. Their advantage is that many programs and operating systems can handle occasional multibyte characters scattered among ordinary ASCII characters, without any change.
- As wide characters, which are like ordinary characters except that they occupy more bits. The wide character data type, wchar_t, has a range large enough to hold extended character codes as well as old-fashioned ASCII codes.

An advantage of wide characters is that each character is a single data object, just like ordinary ASCII characters. There are a few disadvantages:

- Each existing program must be modified and recompiled to make it use wide characters.
- Files of wide characters cannot be read by programs that expect ordinary characters.

Typically, you use the multibyte character representation as part of the external program interface, such as reading or writing text to files. However, it's usually easier to perform internal manipulations on strings containing extended characters on arrays of wchar_t objects, since the uniform representation makes most editing operations easier. If you do use multibyte characters for files and wide characters for internal operations, you need to convert between them when you read and write data.

If your system supports extended characters, then it supports them both as multibyte characters and as wide characters. The library includes functions you can use to convert between the two representations. These functions are described in this chapter.

6.2 Locales and Extended Characters

A computer system can support more than one multibyte character code, and more than one wide character code. The user controls the choice of codes through the current locale for character classification (see Chapter 7 [Locales], page 97). Each locale specifies a particular multibyte character code and a particular wide character code. The choice of locale influences the behavior of the conversion functions in the library.

Some locales support neither wide characters nor nontrivial multibyte characters. In these locales, the library conversion functions still work, even though what they do is basically trivial.

If you select a new locale for character classification, the internal shift state maintained by these functions can become confused, so it's not a good idea to change the locale while you are in the middle of processing a string.

6.3 Multibyte Characters

In the ordinary ASCII code, a sequence of characters is a sequence of bytes, and each character is one byte. This is very simple, but allows for only 256 distinct characters.

In a *multibyte character code*, a sequence of characters is a sequence of bytes, but each character may occupy one or more consecutive bytes of the sequence.

There are many different ways of designing a multibyte character code; different systems use different codes. To specify a particular code means designating the *basic* byte sequences—those which represent a single character—and what characters they stand for. A code that a computer can actually use must have a finite number of these basic sequences, and typically none of them is more than a few characters long.

These sequences need not all have the same length. In fact, many of them are just one byte long. Because the basic ASCII characters in the range from 0 to 0177 are so important, they stand for themselves in all multibyte character codes. That is to say, a byte whose value is 0 through

0177 is always a character in itself. The characters which are more than one byte must always start with a byte in the range from 0200 through 0377.

The byte value 0 can be used to terminated a string, just as it is often used in a string of ASCII characters.

Specifying the basic byte sequences that represent single characters automatically gives meanings to many longer byte sequences, as more than one character. For example, if the two byte sequence 0205 049 stands for the Greek letter alpha, then 0205 049 065 must stand for an alpha followed by an 'A' (ASCII code 065), and 0205 049 0205 049 must stand for two alphas in a row.

If any byte sequence can have more than one meaning as a sequence of characters, then the multibyte code is ambiguous—and no good. The codes that systems actually use are all unambiguous.

In most codes, there are certain sequences of bytes that have no meaning as a character or characters. These are called *invalid*.

The simplest possible multibyte code is a trivial one:

The basic sequences consist of single bytes.

This particular code is equivalent to not using multibyte characters at all. It has no invalid sequences. But it can handle only 256 different characters.

Here is another possible code which can handle 9376 different characters:

The basic sequences consist of

- single bytes with values in the range 0 through 0237.
- two-byte sequences, in which both of the bytes have values in the range from 0240 through 0377.

This code or a similar one is used on some systems to represent Japanese characters. The invalid sequences are those which consist of an odd number of consecutive bytes in the range from 0240 through 0377.

Here is another multibyte code which can handle more distinct extended characters—in fact, almost thirty million:

The basic sequences consist of

- single bytes with values in the range 0 through 0177.
- sequences of up to four bytes in which the first byte is in the range from 0200 through 0237, and the remaining bytes are in the range from 0240 through 0377.

In this code, any sequence that starts with a byte in the range from 0240 through 0377 is invalid.

And here is another variant which has the advantage that removing the last byte or bytes from a valid character can never produce another valid character. (This property is convenient when you want to search strings for particular characters.)

The basic sequences consist of

- single bytes with values in the range 0 through 0177.
- two-byte sequences in which the first byte is in the range from 0200 through 0207, and the second byte is in the range from 0240 through 0377.
- three-byte sequences in which the first byte is in the range from 0210 through 0217, and the other bytes are in the range from 0240 through 0377.
- four-byte sequences in which the first byte is in the range from 0220 through 0227, and the other bytes are in the range from 0240 through 0377.

The list of invalid sequences for this code is long and not worth stating in full; examples of invalid sequences include 0240 and 0220 0300 065.

The number of *possible* multibyte codes is astronomical. But a given computer system will support at most a few different codes. (One of these codes may allow for thousands of different characters.) Another computer system may support a completely different code. The library facilities described in this chapter are helpful because they package up the knowledge of the details of a particular computer system's multibyte code, so your programs need not know them.

You can use special standard macros to find out the maximum possible number of bytes in a character in the currently selected multibyte code with MB_CUR_MAX, and the maximum for any multibyte code supported on your computer with MB_LEN_MAX.

int MB_LEN_MAX Macro

This is the maximum length of a multibyte character for any supported locale. It is defined in 'limits.h'.

int MB_CUR_MAX Macro

This macro expands into a (possibly non-constant) positive integer expression that is the maximum number of bytes in a multibyte character in the current locale. The value is never greater than MB_LEN_MAX.

MB_CUR_MAX is defined in 'stdlib.h'.

Normally, each basic sequence in a particular character code stands for one character, the same character regardless of context. Some multibyte character codes have a concept of *shift state*; certain codes, called *shift sequences*, change to a different shift state, and the meaning of some or all basic sequences varies according to the current shift state. In fact, the set of basic sequences might even be different depending on the current shift state. See Section 6.9 [Shift State], page 94, for more information on handling this sort of code.

What happens if you try to pass a string containing multibyte characters to a function that doesn't know about them? Normally, such a function treats a string as a sequence of bytes, and interprets certain byte values specially; all other byte values are "ordinary". As long as a multibyte character doesn't contain any of the special byte values, the function should pass it through as if it were several ordinary characters.

For example, let's figure out what happens if you use multibyte characters in a file name. The functions such as open and unlink that operate on file names treat the name as a sequence of byte values, with '/' as the only special value. Any other byte values are copied, or compared, in sequence, and all byte values are treated alike. Thus, you may think of the file name as a sequence of bytes or as a string containing multibyte characters; the same behavior makes sense equally either way, provided no multibyte character contains a '/'.

6.4 Wide Character Introduction

Wide characters are much simpler than multibyte characters. They are simply characters with more than eight bits, so that they have room for more than 256 distinct codes. The wide character data type, wchar_t, has a range large enough to hold extended character codes as well as old-fashioned ASCII codes.

An advantage of wide characters is that each character is a single data object, just like ordinary ASCII characters. Wide characters also have some disadvantages:

- A program must be modified and recompiled in order to use wide characters at all.
- Files of wide characters cannot be read by programs that expect ordinary characters.

Wide character values 0 through 0177 are always identical in meaning to the ASCII character codes. The wide character value zero is often used to terminate a string of wide characters, just as a single byte with value zero often terminates a string of ordinary characters.

wchar_t Data Type

This is the "wide character" type, an integer type whose range is large enough to represent all distinct values in any extended character set in the supported locales. See Chapter 7 [Locales], page 97, for more information about locales. This type is defined in the header file 'stddef.h'.

If your system supports extended characters, then each extended character has both a wide character code and a corresponding multibyte basic sequence.

In this chapter, the term *code* is used to refer to a single extended character object to emphasize the distinction from the **char** data type.

6.5 Conversion of Extended Strings

The mbstowcs function converts a string of multibyte characters to a wide character array. The wcstombs function does the reverse. These functions are declared in the header file 'stdlib.h'.

In most programs, these functions are the only ones you need for conversion between wide strings and multibyte character strings. But they have limitations. If your data is not null-terminated or is not all in core at once, you probably need to use the low-level conversion functions to convert one character at a time. See Section 6.7 [Converting One Char], page 90.

size_t mbstowcs (wchar_t *wstring, const char *string, size_t size) Function
The mbstowcs ("multibyte string to wide character string") function converts the nullterminated string of multibyte characters string to an array of wide character codes,

storing not more than size wide characters into the array beginning at wstring. The terminating null character counts towards the size, so if size is less than the actual number of wide characters resulting from string, no terminating null character is stored.

The conversion of characters from string begins in the initial shift state.

If an invalid multibyte character sequence is found, this function returns a value of -1. Otherwise, it returns the number of wide characters stored in the array wstring. This number does not include the terminating null character, which is present if the number is less than size.

Here is an example showing how to convert a string of multibyte characters, allocating enough space for the result.

```
wchar_t *
mbstowcs_alloc (char *string)
{
  int size = strlen (string) + 1;
  wchar_t *buffer = (wchar_t) xmalloc (size * sizeof (wchar_t));

  size = mbstowcs (buffer, string, size);
  if (size < 0)
    return NULL;
  return (wchar_t) xrealloc (buffer, (size + 1) * sizeof (wchar_t));
}</pre>
```

```
size_t wcstombs (char *string, const wchar_t wstring, size_t size) Function
```

The wcstombs ("wide character string to multibyte string") function converts the null-terminated wide character array wstring into a string containing multibyte characters, storing not more than size bytes starting at string, followed by a terminating null character if there is room. The conversion of characters begins in the initial shift state.

The terminating null character counts towards the size, so if size is less than or equal to the number of bytes needed in wstring, no terminating null character is stored.

If a code that does not correspond to a valid multibyte character is found, this function returns a value of -1. Otherwise, the return value is the number of bytes stored in the array *string*. This number does not include the terminating null character, which is present if the number is less than *size*.

6.6 Multibyte Character Length

This section describes how to scan a string containing multibyte characters, one character at a time. The difficulty in doing this is to know how many bytes each character contains. Your program can use mblen to find this out.

int mblen (const char *string, size_t size)

Function

The mblen function with non-null *string* returns the number of bytes that make up the multibyte character beginning at *string*, never examining more than *size* bytes. (The idea is to supply for *size* the number of bytes of data you have in hand.)

The return value of mblen distinguishes three possibilities: the first size bytes at string start with valid multibyte character, they start with an invalid byte sequence or just part of a character, or string points to an empty string (a null character).

For a valid multibyte character, mblen returns the number of bytes in that character (always at least 1, and never more than *size*). For an invalid byte sequence, mblen returns -1. For an empty string, it returns 0.

If the multibyte character code uses shift characters, then mblen maintains and updates a shift state as it scans. If you call mblen with a null pointer for *string*, that initializes the shift state to its standard initial value. It also returns nonzero if the multibyte character code in use actually has a shift state. See Section 6.9 [Shift State], page 94.

The function mblen is declared in 'stdlib.h'.

6.7 Conversion of Extended Characters One by One

You can convert multibyte characters one at a time to wide characters with the mbtowc function. The wctomb function does the reverse. These functions are declared in 'stdlib.h'.

int mbtowc (wchar_t *result, const char *string, size_t size)

Function

The mbtowc ("multibyte to wide character") function when called with non-null string converts the first multibyte character beginning at string to its corresponding wide character code. It stores the result in *result.

mbtowc never examines more than size bytes. (The idea is to supply for size the number of bytes of data you have in hand.)

mbtowc with non-null *string* distinguishes three possibilities: the first *size* bytes at *string* start with valid multibyte character, they start with an invalid byte sequence or just part of a character, or *string* points to an empty string (a null character).

For a valid multibyte character, mbtowc converts it to a wide character and stores that in *result, and returns the number of bytes in that character (always at least 1, and never more than size).

For an invalid byte sequence, mbtowc returns -1. For an empty string, it returns 0, also storing 0 in *result.

If the multibyte character code uses shift characters, then mbtowc maintains and updates a shift state as it scans. If you call mbtowc with a null pointer for *string*, that initializes the shift state to its standard initial value. It also returns nonzero if the multibyte character code in use actually has a shift state. See Section 6.9 [Shift State], page 94.

int wctomb (char *string, wchar_t wchar)

Function

The wctomb ("wide character to multibyte") function converts the wide character code wchar to its corresponding multibyte character sequence, and stores the result in bytes starting at string. At most MB_CUR_MAX characters are stored.

wctomb with non-null *string* distinguishes three possibilities for *wchar*: a valid wide character code (one that can be translated to a multibyte character), an invalid code, and 0.

Given a valid code, wctomb converts it to a multibyte character, storing the bytes starting at *string*. Then it returns the number of bytes in that character (always at least 1, and never more than MB_CUR_MAX).

If wchar is an invalid wide character code, wctomb returns -1. If wchar is 0, it returns 0, also storing 0 in *string.

If the multibyte character code uses shift characters, then wctomb maintains and updates a shift state as it scans. If you call wctomb with a null pointer for string, that

initializes the shift state to its standard initial value. It also returns nonzero if the multibyte character code in use actually has a shift state. See Section 6.9 [Shift State], page 94.

Calling this function with a *wchar* argument of zero when *string* is not null has the side-effect of reinitializing the stored shift state as *well* as storing the multibyte character 0 and returning 0.

6.8 Example of Character-by-Character Conversion

Here is an example that reads multibyte character text from descriptor input and writes the corresponding wide characters to descriptor output. We need to convert characters one by one for this example because mbstowcs is unable to continue past a null character, and cannot cope with an apparently invalid partial character by reading more input.

```
int
file_mbstowcs (int input, int output)
  char buffer[BUFSIZ + MB_LEN_MAX];
  int filled = 0;
  int eof = 0;
  while (!eof)
    {
      int nread;
      int nwrite;
      char *inp = buffer;
      wchar_t outbuf[BUFSIZ];
      wchar_t *outp = outbuf;
      /* Fill up the buffer from the input file. */
      nread = read (input, buffer + filled, BUFSIZ);
      if (nread < 0) {
        perror ("read");
        return 0;
      /* If we reach end of file, make a note to read no more. */
      if (nread == 0)
        eof = 1:
      /* filled is now the number of bytes in buffer. */
      filled += nread;
```

```
/* Convert those bytes to wide characters—as many as we can. */
      while (1)
        {
          int thislen = mbtowc (outp, inp, filled);
          /* Stop converting at invalid character;
              this can mean we have read just the first part
              of a valid character. */
          if (thislen == -1)
            break;
          /* Treat null character like any other,
              but also reset shift state. */
          if (thislen == 0) {
             thislen = 1;
            mbtowc (NULL, NULL, 0);
          /* Advance past this character. */
          inp += thislen;
          filled -= thislen;
          outp++;
      /* Write the wide characters we just made. */
      nwrite = write (output, outbuf,
                       (outp - outbuf) * sizeof (wchar_t));
      if (nwrite < 0)
          perror ("write");
          return 0;
      /* See if we have a real invalid character. */
      if ((eof && filled > 0) || filled >= MB_CUR_MAX)
          error ("invalid multibyte character");
          return 0;
      /* If any characters must be carried forward,
      put them at the beginning of buffer. */
      if (filled > 0)
        memcpy (inp, buffer, filled);
    }
 return 1;
}
```

6.9 Multibyte Codes Using Shift Sequences

In some multibyte character codes, the *meaning* of any particular byte sequence is not fixed; it depends on what other sequences have come earlier in the same string. Typically there are just a few sequences that can change the meaning of other sequences; these few are called *shift sequences* and we say that they set the *shift state* for other sequences that follow.

To illustrate shift state and shift sequences, suppose we decide that the sequence 0200 (just one byte) enters Japanese mode, in which pairs of bytes in the range from 0240 to 0377 are single characters, while 0201 enters Latin-1 mode, in which single bytes in the range from 0240 to 0377 are characters, and interpreted according to the ISO Latin-1 character set. This is a multibyte code which has two alternative shift states ("Japanese mode" and "Latin-1 mode"), and two shift sequences that specify particular shift states.

When the multibyte character code in use has shift states, then mblen, mbtowc and wctomb must maintain and update the current shift state as they scan the string. To make this work properly, you must follow these rules:

- Before starting to scan a string, call the function with a null pointer for the multibyte character address—for example, mblen (NULL, 0). This initializes the shift state to its standard initial value.
- Scan the string one character at a time, in order. Do not "back up" and rescan characters already scanned, and do not intersperse the processing of different strings.

Here is an example of using mblen following these rules:

```
void
scan_string (char *s)
{
  int length = strlen (s);
  /* Initialize shift state. */
  mblen (NULL, 0);
```

```
while (1)
{
   int thischar = mblen (s, length);
   /* Deal with end of string and invalid characters. */
   if (thischar == 0)
      break;
   if (thischar == -1)
      {
       error ("invalid multibyte character");
      break;
    }
   /* Advance past this character. */
   s += thischar;
   length -= thischar;
}
```

The functions mblen, mbtowc and wctomb are not reentrant when using a multibyte code that uses a shift state. However, no other library functions call these functions, so you don't have to worry that the shift state will be changed mysteriously.

96

7 Locales and Internationalization

Different countries and cultures have varying conventions for how to communicate. These conventions range from very simple ones, such as the format for representing dates and times, to very complex ones, such as the language spoken.

Internationalization of software means programming it to be able to adapt to the user's favorite conventions. In ANSI C, internationalization works by means of *locales*. Each locale specifies a collection of conventions, one convention for each purpose. The user chooses a set of conventions by specifying a locale (via environment variables).

All programs inherit the chosen locale as part of their environment. Provided the programs are written to obey the choice of locale, they will follow the conventions preferred by the user.

7.1 What Effects a Locale Has

Each locale specifies conventions for several purposes, including the following:

- What multibyte character sequences are valid, and how they are interpreted (see Chapter 6 [Extended Characters], page 83).
- Classification of which characters in the local character set are considered alphabetic, and upper- and lower-case conversion conventions (see Chapter 4 [Character Handling], page 61).
- The collating sequence for the local language and character set (see Section 5.6 [Collation Functions], page 74).
- Formatting of numbers and currency amounts.
- Formatting of dates and times (see Section 19.2.4 [Formatting Date and Time], page 380).
- What language to use for output, including error messages. (The C library doesn't yet help you implement this.)
- What language to use for user answers to yes-or-no questions.
- What language to use for more complex user input. (The C library doesn't yet help you implement this.)

Some aspects of adapting to the specified locale are handled automatically by the library subroutines. For example, all your program needs to do in order to use the collating sequence of the chosen locale is to use strcoll or strxfrm to compare strings.

Other aspects of locales are beyond the comprehension of the library. For example, the library can't automatically translate your program's output messages into other languages. The only way you can support output in the user's favorite language is to program this more or less by hand. (Eventually, we hope to provide facilities to make this easier.)

This chapter discusses the mechanism by which you can modify the current locale. The effects of the current locale on specific library functions are discussed in more detail in the descriptions of those functions.

7.2 Choosing a Locale

The simplest way for the user to choose a locale is to set the environment variable LANG. This specifies a single locale to use for all purposes. For example, a user could specify a hypothetical locale named 'espana-castellano' to use the standard conventions of most of Spain.

The set of locales supported depends on the operating system you are using, and so do their names. We can't make any promises about what locales will exist, except for one standard locale called 'C' or 'POSIX'.

A user also has the option of specifying different locales for different purposes—in effect, choosing a mixture of two locales.

For example, the user might specify the locale 'espana-castellano' for most purposes, but specify the locale 'usa-english' for currency formatting. This might make sense if the user is a Spanish-speaking American, working in Spanish, but representing monetary amounts in US dollars.

Note that both locales 'espana-castellano' and 'usa-english', like all locales, would include conventions for all of the purposes to which locales apply. However, the user can choose to use each locale for a particular subset of those purposes.

7.3 Categories of Activities that Locales Affect

The purposes that locales serve are grouped into *categories*, so that a user or a program can choose the locale for each category independently. Here is a table of categories; each name is both an environment variable that a user can set, and a macro name that you can use as an argument to setlocale.

LC_COLLATE

This category applies to collation of strings (functions strcoll and strxfrm); see Section 5.6 [Collation Functions], page 74.

LC_CTYPE This category applies to classification and conversion of characters; see Chapter 4 [Character Handling], page 61.

LC_MONETARY

This category applies to formatting monetary values; see Section 7.6 [Numeric Formatting], page 102.

LC_NUMERIC

This category applies to formatting numeric values that are not monetary; see Section 7.6 [Numeric Formatting], page 102.

- LC_TIME This category applies to formatting date and time values; see Section 19.2.4 [Formatting Date and Time], page 380.
- LC_ALL This is not an environment variable; it is only a macro that you can use with setlocale to set a single locale for all purposes.
- LANG If this environment variable is defined, its value specifies the locale to use for all purposes except as overridden by the variables above.

7.4 How Programs Set the Locale

A C program inherits its locale environment variables when it starts up. This happens automatically. However, these variables do not automatically control the locale used by the library functions, because ANSI C says that all programs start by default in the standard 'C' locale. To use the locales specified by the environment, you must call setlocale. Call it as follows:

```
setlocale (LC_ALL, "");
```

to select a locale based on the appropriate environment variables.

You can also use **setlocale** to specify a particular locale, for general use or for a specific category.

The symbols in this section are defined in the header file 'locale.h'.

100 The GNU C Library

char * setlocale (int category, const char *locale)

Function

The function setlocale sets the current locale for category category to locale.

If category is LC_ALL, this specifies the locale for all purposes. The other possible values of category specify an individual purpose (see Section 7.3 [Locale Categories], page 98).

You can also use this function to find out the current locale by passing a null pointer as the *locale* argument. In this case, **setlocale** returns a string that is the name of the locale currently selected for category category.

The string returned by setlocale can be overwritten by subsequent calls, so you should make a copy of the string (see Section 5.4 [Copying and Concatenation], page 67) if you want to save it past any further calls to setlocale. (The standard library is guaranteed never to call setlocale itself.)

You should not modify the string returned by setlocale. It might be the same string that was passed as an argument in a previous call to setlocale.

When you read the current locale for category LC_ALL, the value encodes the entire combination of selected locales for all categories. In this case, the value is not just a single locale name. In fact, we don't make any promises about what it looks like. But if you specify the same "locale name" with LC_ALL in a subsequent call to setlocale, it restores the same combination of locale selections.

When the *locale* argument is not a null pointer, the string returned by setlocale reflects the newly modified locale.

If you specify an empty string for *locale*, this means to read the appropriate environment variable and use its value to select the locale for *category*.

If you specify an invalid locale name, setlocale returns a null pointer and leaves the current locale unchanged.

Here is an example showing how you might use setlocale to temporarily switch to a new locale.

```
#include <stddef.h>
#include <locale.h>
#include <stdlib.h>
```

```
#include <string.h>
void
with_other_locale (char *new_locale,
                    void (*subroutine) (int),
                    int argument)
{
  char *old_locale, *saved_locale;
  /* Get the name of the current locale. */
  old_locale = setlocale (LC_ALL, NULL);
  /* Copy the name so it won't be clobbered by setlocale. */
  saved_locale = strdup (old_locale);
  if (old_locale == NULL)
    fatal ("Out of memory");
  /* Now change the locale and do some stuff with it. */
  setlocale (LC_ALL, new_locale);
  (*subroutine) (argument);
  /* Restore the original locale. */
  setlocale (LC_ALL, saved_locale);
  free (saved_locale);
}
```

Portability Note: Some ANSI C systems may define additional locale categories. For portability, assume that any symbol beginning with 'LC_' might be defined in 'locale.h'.

7.5 Standard Locales

The only locale names you can count on finding on all operating systems are these three standard ones:

"C" This is the standard C locale. The attributes and behavior it provides are specified in the ANSI C standard. When your program starts up, it initially uses this locale by default.

"POSIX" This is the standard POSIX locale. Currently, it is an alias for the standard C locale.

"" The empty name stands for a site-specific default locale. It's supposed to be a good default for the machine on which the program is running.

102 The GNU C Library

Defining and installing named locales is normally a responsibility of the system administrator at your site (or the person who installed the GNU C library). Some systems may allow users to create locales, but we don't discuss that here.

If your program needs to use something other than the 'C' locale, it will be more portable if you use the whatever locale the user specifies with the environment, rather than trying to specify some non-standard locale explicitly by name. Remember, different machines might have different sets of locales installed.

7.6 Numeric Formatting

When you want to format a number or a currency amount using the conventions of the current locale, you can use the function localeconv to get the data on how to do it. The function localeconv is declared in the header file 'locale.h'.

struct lconv * localeconv (void)

Function

The localeconv function returns a pointer to a structure whose components contain information about how numeric and monetary values should be formatted in the current locale.

You shouldn't modify the structure or its contents. The structure might be overwritten by subsequent calls to localeconv, or by calls to setlocale, but no other function in the library overwrites this value.

struct lconv Data Type

This is the data type of the value returned by localeconv.

If a member of the structure struct lconv has type char, and the value is CHAR_MAX, it means that the current locale has no value for that parameter.

7.6.1 Generic Numeric Formatting Parameters

These are the standard members of struct lconv; there may be others.

char *decimal_point
char *mon_decimal_point

These are the decimal-point separators used in formatting non-monetary and monetary quantities, respectively. In the 'C' locale, the value of decimal_point is ".", and the value of mon_decimal_point is "".

char *thousands_sep
char *mon_thousands_sep

These are the separators used to delimit groups of digits to the left of the decimal point in formatting non-monetary and monetary quantities, respectively. In the 'C' locale, both members have a value of "" (the empty string).

char *grouping
char *mon_grouping

These are strings that specify how to group the digits to the left of the decimal point. grouping applies to non-monetary quantities and mon_grouping applies to monetary quantities. Use either thousands_sep or mon_thousands_sep to separate the digit groups.

Each string is made up of decimal numbers separated by semicolons. Successive numbers (from left to right) give the sizes of successive groups (from right to left, starting at the decimal point). The last number in the string is used over and over for all the remaining groups.

If the last integer is -1, it means that there is no more grouping—or, put another way, any remaining digits form one large group without separators.

For example, if grouping is "4;3;2", the number 123456787654321 should be grouped into '12', '34', '56', '78', '765', '4321'. This uses a group of 4 digits at the end, preceded by a group of 3 digits, preceded by groups of 2 digits (as many as needed). With a separator of ',', the number would be printed as '12,34,56,78,765,4321'.

A value of "3" indicates repeated groups of three digits, as normally used in the U.S. In the standard 'C' locale, both grouping and mon_grouping have a value of "". This value specifies no grouping at all.

char int_frac_digits
char frac_digits

These are small integers indicating how many fractional digits (to the right of the decimal point) should be displayed in a monetary value in international and local formats, respectively. (Most often, both members have the same value.)

In the standard 'C' locale, both of these members have the value CHAR_MAX, meaning "unspecified". The ANSI standard doesn't say what to do when you find this the value; we recommend printing no fractional digits. (This locale also specifies the empty string for mon_decimal_point, so printing any fractional digits would be confusing!)

104 The GNU C Library

7.6.2 Printing the Currency Symbol

These members of the **structlconv** structure specify how to print the symbol to identify a monetary value—the international analog of '\$' for US dollars.

Each country has two standard currency symbols. The *local currency symbol* is used commonly within the country, while the *international currency symbol* is used internationally to refer to that country's currency when it is necessary to indicate the country unambiguously.

For example, many countries use the dollar as their monetary unit, and when dealing with international currencies it's important to specify that one is dealing with (say) Canadian dollars instead of U.S. dollars or Australian dollars. But when the context is known to be Canada, there is no need to make this explicit—dollar amounts are implicitly assumed to be in Canadian dollars.

char *currency_symbol

The local currency symbol for the selected locale.

In the standard 'C' locale, this member has a value of "" (the empty string), meaning "unspecified". The ANSI standard doesn't say what to do when you find this value; we recommend you simply print the empty string as you would print any other string found in the appropriate member.

char *int_curr_symbol

The international currency symbol for the selected locale.

The value of int_curr_symbol should normally consist of a three-letter abbreviation determined by the international standard ISO 4217 Codes for the Representation of Currency and Funds, followed by a one-character separator (often a space).

In the standard 'C' locale, this member has a value of "" (the empty string), meaning "unspecified". We recommend you simply print the empty string as you would print any other string found in the appropriate member.

char p_cs_precedes char n_cs_precedes

These members are 1 if the currency_symbol string should precede the value of a monetary amount, or 0 if the string should follow the value. The p_cs_precedes member applies to positive amounts (or zero), and the n_cs_precedes member applies to negative amounts.

In the standard 'C' locale, both of these members have a value of CHAR_MAX, meaning "unspecified". The ANSI standard doesn't say what to do when you find this value, but we recommend printing the currency symbol before the amount. That's right for most countries. In other words, treat all nonzero values alike in these members.

The POSIX standard says that these two members apply to the int_curr_symbol as well as the currency_symbol. The ANSI C standard seems to imply that they should apply only to the currency_symbol—so the int_curr_symbol should always preced the amount.

We can only guess which of these (if either) matches the usual conventions for printing international currency symbols. Our guess is that they should always preced the amount. If we find out a reliable answer, we will put it here.

```
char p_sep_by_space
char n_sep_by_space
```

These members are 1 if a space should appear between the currency_symbol string and the amount, or 0 if no space should appear. The p_sep_by_space member applies to positive amounts (or zero), and the n_sep_by_space member applies to negative amounts.

In the standard 'C' locale, both of these members have a value of CHAR_MAX, meaning "unspecified". The ANSI standard doesn't say what you should do when you find this value; we suggest you treat it as one (print a space). In other words, treat all nonzero values alike in these members.

These members apply only to currency_symbol. When you use int_curr_symbol, you never print an additional space, because int_curr_symbol itself contains the appropriate separator.

The POSIX standard says that these two members apply to the int_curr_symbol as well as the currency_symbol. But an example in the ANSI C standard clearly implies that they should apply only to the currency_symbol—that the int_curr_symbol contains any appropriate separator, so you should never print an additional space.

Based on what we know now, we recommend you ignore these members when printing international currency symbols, and print no extra space.

7.6.3 Printing the Sign of an Amount of Money

These members of the **struct lconv** structure specify how to print the sign (if any) in a monetary value.

```
char *positive_sign
char *negative_sign
```

These are strings used to indicate positive (or zero) and negative (respectively) monetary quantities.

In the standard 'C' locale, both of these members have a value of "" (the empty string), meaning "unspecified".

The ANSI standard doesn't say what to do when you find this value; we recommend printing positive_sign as you find it, even if it is empty. For a negative value, print negative_sign as you find it unless both it and positive_sign are empty, in which case print '-' instead. (Failing to indicate the sign at all seems rather unreasonable.)

char p_sign_posn
char n_sign_posn

These members have values that are small integers indicating how to position the sign for nonnegative and negative monetary quantities, respectively. (The string used by the sign is what was specified with positive_sign or negative_sign.) The possible values are as follows:

- The currency symbol and quantity should be surrounded by parentheses.
- 1 Print the sign string before the quantity and currency symbol.
- 2 Print the sign string after the quantity and currency symbol.
- 3 Print the sign string right before the currency symbol.
- 4 Print the sign string right after the currency symbol.

CHAR_MAX "Unspecified". Both members have this value in the standard 'C' locale.

The ANSI standard doesn't say what you should do when the value is CHAR_MAX. We recommend you print the sign after the currency symbol.

It is not clear whether you should let these members apply to the international currency format or not. POSIX says you should, but intuition plus the examples in the ANSI C standard suggest you should not. We hope that someone who knows well the conventions for formatting monetary quantities will tell us what we should recommend.

8 Searching and Sorting

This chapter describes functions for searching and sorting arrays of arbitrary objects. You pass the appropriate comparison function to be applied as an argument, along with the size of the objects in the array and the total number of elements.

8.1 Defining the Comparison Function

In order to use the sorted array library functions, you have to describe how to compare the elements of the array.

To do this, you supply a comparison function to compare two elements of the array. The library will call this function, passing as arguments pointers to two array elements to be compared. Your comparison function should return a value the way strcmp (see Section 5.5 [String/Array Comparison], page 72) does: negative if the first argument is "less" than the second, zero if they are "equal", and positive if the first argument is "greater".

Here is an example of a comparison function which works with an array of numbers of type double:

```
compare_doubles (const double *a, const double *b)
{
  double temp = *a - *b;
  if (temp > 0)
    return 1;
  else if (temp < 0)
    return -1;
  else
    return 0;
}</pre>
```

The header file 'stdlib.h' defines a name for the data type of comparison functions. This is a GNU extension and thus defined only if you request the GNU extensions.

```
int comparison_fn_t (const void *, const void *);
```

8.2 Array Search Function

To search a sorted array for an element matching the key, use the bsearch function. The prototype for this function is in the header file 'stdlib.h'.

The bsearch function searches the sorted array array for an object that is equivalent to key. The array contains count elements, each of which is of size size.

The compare function is used to perform the comparison. This function is called with two pointer arguments and should return an integer less than, equal to, or greater than zero corresponding to whether its first argument is considered less than, equal to, or greater than its second argument. The elements of the array must already be sorted in ascending order according to this comparison function.

The return value is a pointer to the matching array element, or a null pointer if no match is found. If the array contains more than one element that matches, the one that is returned is unspecified.

This function derives its name from the fact that it is implemented using the binary search.

8.3 Array Sort Function

To sort an array using an arbitrary comparison function, use the qsort function. The prototype for this function is in 'stdlib.h'.

The qsort function sorts the array array. The array contains count elements, each of which is of size size.

The compare function is used to perform the comparison on the array elements. This function is called with two pointer arguments and should return an integer less than, equal to, or greater than zero corresponding to whether its first argument is considered less than, equal to, or greater than its second argument.

Warning: If two objects compare as equal, their order after sorting is unpredictable. That is to say, the sorting is not stable. This can make a difference when the comparison considers only part of the elements. Two elements with the same sort key may differ in other respects.

If you want the effect of a stable sort, you can get this result by writing the comparison function so that, lacking other reason distinguish between two elements, it compares them by their addresses.

Here is a simple example of sorting an array of doubles in numerical order, using the comparison function defined above (see Section 8.1 [Comparison Functions], page 107):

```
{
  double *array;
  int size;
  ...
  qsort (array, size, sizeof (double), compare_doubles);
}
```

The qsort function derives its name from the fact that it was originally implemented using the algorithm "quick sort".

8.4 Searching and Sorting Example

Here is an example showing the use of qsort and bsearch with an array of structures. The objects in the array are sorted by comparing their name fields with the strcmp function. Then, we can look up individual objects based on their names.

```
#include <stdlib.h>
#include <stdio.h>
#include <string.h>

/* Define an array of critters to sort. */
struct critter
{
   char *name;
   char *species;
};
```

```
struct critter muppets[]=
  {"Kermit", "frog"},
  {"Piggy", "pig"},
{"Gonzo", "whatever"},
{"Fozzie", "bear"},
  {"Sam", "eagle"},
  {"Robin", "frog"},
{"Animal", "animal"},
{"Camilla", "chicken"},
  {"Sweetums", "monster"},
  {"Dr. Strangepork", "pig"},
{"Link Hogthrob", "pig"},
  {"Zoot", "human"},
  {"Dr. Bunsen Honeydew", "human"},
  {"Beaker", "human"},
  {"Swedish Chef", "human"}};
int count = sizeof (muppets) / sizeof (struct critter);
/* This is the comparison function used for sorting and searching. */
int
critter_cmp (const struct critter *c1, const struct critter *c2)
  return strcmp (c1->name, c2->name);
/* Print information about a critter. */
void
print_critter (const struct critter *c)
  printf ("%s, the %s\n", c->name, c->species);
```

```
/* Do the lookup into the sorted array. */
void
find_critter (char *name)
  struct critter target, *result;
  target.name = name;
  result = bsearch (&target, muppets, count, sizeof (struct critter),
    critter_cmp);
  if (result)
    print_critter (result);
    printf ("Couldn't find %s.\n", name);
}
/* Main program. */
int
main (void)
{
  int i;
  for (i = 0; i < count; i++)
    print_critter (&muppets[i]);
  printf ("\n");
  qsort (muppets, count, sizeof (struct critter), critter_cmp);
  for (i = 0; i < count; i++)
    print_critter (&muppets[i]);
  printf ("\n");
  find_critter ("Kermit");
  find_critter ("Gonzo");
  find_critter ("Janice");
  return 0;
}
```

The output from this program looks like:

```
Animal, the animal
Beaker, the human
Camilla, the chicken
```

Dr. Bunsen Honeydew, the human Dr. Strangepork, the pig Fozzie, the bear Gonzo, the whatever Kermit, the frog Link Hogthrob, the pig Piggy, the pig Robin, the frog Sam, the eagle Swedish Chef, the human Sweetums, the monster Zoot, the human

Kermit, the frog Gonzo, the whatever Couldn't find Janice.

9 Pattern Matching

The GNU C Library provides pattern matching facilities for two kinds of patterns: regular expressions and file-name wildcards.

9.1 Wildcard Matching

This section describes how to match a wildcard pattern against a particular string. The result is a yes or no answer: does the string fit the pattern or not. The symbols described here are all declared in 'fnmatch.h'.

int fnmatch (const char *pattern, const char *string, int flags) Function

This function tests whether the string string matches the pattern pattern. It returns 0 if they do match; otherwise, it returns the nonzero value FNM_NOMATCH. The arguments pattern and string are both strings.

The argument flags is a combination of flag bits that alter the details of matching. See below for a list of the defined flags.

In the GNU C Library, fnmatch cannot experience an "error"—it always returns an answer for whether the match succeeds. However, other implementations of fnmatch might sometimes report "errors". They would do so by returning nonzero values that are not equal to FNM_NOMATCH.

These are the available flags for the flags argument:

FNM_FILE_NAME

Treat the '/' character specially, for matching file names. If this flag is set, wildcard constructs in *pattern* cannot match '/' in *string*. Thus, the only way to match '/' is with an explicit '/' in *pattern*.

FNM_PATHNAME

This is an alias for FNM_FILE_NAME; it comes from POSIX.2. We don't recommend this name because we don't use the term "pathname" for file names.

FNM_PERIOD

Treat the '.' character specially if it appears at the beginning of string. If this flag is set, wildcard constructs in pattern cannot match '.' as the first character of string.

If you set both FNM_PERIOD and FNM_FILE_NAME, then the special treatment applies to '.' following '/' as well as to '.' at the beginning of string.

FNM_NOESCAPE

Don't treat the '\' character specially in patterns. Normally, '\' quotes the following character, turning off its special meaning (if any) so that it matches only itself. When quoting is enabled, the pattern '\?' matches only the string '?', because the question mark in the pattern acts like an ordinary character.

If you use FNM_NOESCAPE, then '\' is an ordinary character.

FNM_LEADING_DIR

Ignore a trailing sequence of characters starting with a '/' in *string*; that is to say, test whether *string* starts with a directory name that *pattern* matches.

If this flag is set, either 'foo*' or 'foobar' as a pattern would match the string 'foobar/frobozz'.

FNM_CASEFOLD

Ignore case in comparing string to pattern.

9.2 Globbing

The archetypal use of wildcards is for matching against the files in a directory, and making a list of all the matches. This is called *globbing*.

You could do this using fnmatch, by reading the directory entries one by one and testing each one with fnmatch. But that would be slow (and complex, since you would have to handle subdirectories by hand).

The library provides a function glob to make this particular use of wildcards convenient. glob and the other symbols in this section are declared in 'glob.h'.

9.2.1 Calling glob

The result of globbing is a vector of file names (strings). To return this vector, glob uses a special data type, glob_t, which is a structure. You pass glob the address of the structure, and it fills in the structure's fields to tell you about the results.

glob_t Data Type

This data type holds a pointer to a word vector. More precisely, it records both the address of the word vector and its size.

gl_pathc The number of elements in the vector.

gl_pathv The address of the vector. This field has type char **.

gl_offs The offset of the first real element of the vector, from its nominal address in the gl_pathv field. Unlike the other fields, this is always an input to glob, rather than an output from it.

If you use a nonzero offset, then that many elements at the beginning of the vector are left empty. (The glob function fills them with null pointers.)

The gl_offs field is meaningful only if you use the GLOB_DOOFFS flag. Otherwise, the offset is always zero regardless of what is in this field, and the first real element comes at the beginning of the vector.

The function glob does globbing using the pattern pattern in the current directory. It puts the result in a newly allocated vector, and stores the size and address of this vector into *vector-ptr. The argument flags is a combination of bit flags; see Section 9.2.2 [Flags for Globbing], page 116, for details of the flags.

The result of globbing is a sequence of file names. The function glob allocates a string for each resulting word, then allocates a vector of type char ** to store the addresses of these strings. The last element of the vector is a null pointer. This vector is called the word vector.

To return this vector, glob stores both its address and its length (number of elements, not counting the terminating null pointer) into *vector-ptr.

Normally, glob sorts the file names alphabetically before returning them. You can turn this off with the flag GLOB_NOSORT if you want to get the information as fast as possible. Usually it's a good idea to let glob sort them—if you process the files in alphabetical order, the users will have a feel for the rate of progress that your application is making.

If glob succeeds, it returns 0. Otherwise, it returns one of these error codes:

GLOB_ABORTED

There was an error opening a directory, and you used the flag GLOB_ERR or your specified *errfunc* returned a nonzero value.

GLOB_NOMATCH

The pattern didn't match any existing files. If you use the GLOB_NOCHECK flag, then you never get this error code, because that flag tells glob to pretend that the pattern matched at least one file.

GLOB_NOSPACE

It was impossible to allocate memory to hold the result.

In the event of an error, glob stores information in *vector-ptr about all the matches it has found so far.

9.2.2 Flags for Globbing

This section describes the flags that you can specify in the flags argument to glob. Choose the flags you want, and combine them with the C operator |.

GLOB_APPEND

Append the words from this expansion to the vector of words produced by previous calls to glob. This way you can effectively expand several words as if they were concatenated with spaces between them.

In order for appending to work, you must not modify the contents of the word vector structure between calls to glob. And, if you set GLOB_DOOFFS in the first call to glob, you must also set it when you append to the results.

GLOB_DOOFFS

Leave blank slots at the beginning of the vector of words. The gl_offs field says how many slots to leave. The blank slots contain null pointers.

GLOB_ERR Give up right away and report an error if there is any difficulty reading the directories that must be read in order to expand pattern fully. Such difficulties might include a directory in which you don't have the requisite access. Normally, glob tries its best to keep on going despite any errors, reading whatever directories it can.

You can exercise even more control than this by specifying an error-handler function errfunc when you call glob. If errfunc is nonzero, then glob doesn't give up right away when it can't read a directory; instead, it calls errfunc with two arguments, like this:

(*errfunc) (filename, error-code)

The argument *filename* is the name of the directory that glob couldn't open or couldn't read, and *error-code* is the errno value that was reported to glob.

If the error handler function returns nonzero, then glob gives up right away. Otherwise, it continues.

GLOB_MARK

If the pattern matches the name of a directory, append '/' to the directory's name when returning it.

GLOB_NOCHECK

If the pattern doesn't match any file names, return the pattern itself as if it were a file name that had been matched. (Normally, when the pattern doesn't match anything, glob returns that there were no matches.)

GLOB_NOSORT

Don't sort the file names; return them in no particular order. (In practice, the order will depend on the order of the entries in the directory.) The only reason *not* to sort is to save time.

GLOB_NOESCAPE

Don't treat the '\' character specially in patterns. Normally, '\' quotes the following character, turning off its special meaning (if any) so that it matches only itself. When quoting is enabled, the pattern '\?' matches only the string '?', because the question mark in the pattern acts like an ordinary character.

If you use GLOB_NOESCAPE, then '\' is an ordinary character.

glob does its work by calling the function fnmatch repeatedly. It handles the flag GLOB_NOESCAPE by turning on the FNM_NOESCAPE flag in calls to fnmatch.

9.3 Regular Expression Matching

The GNU C library supports two interfaces for matching regular expressions. One is the standard POSIX.2 interface, and the other is what the GNU system has had for many years.

Both interfaces are declared in the header file 'regex.h'. If you define _GNU_SOURCE, then the GNU functions, structures and constants are declared. Otherwise, only the POSIX names are declared.

9.3.1 POSIX Regular Expression Compilation

Before you can actually match a regular expression, you must *compile* it. This is not true compilation—it produces a special data structure, not machine instructions. But it is like ordinary compilation in that its purpose is to enable you to "execute" the pattern fast. (See Section 9.3.3 [Matching POSIX Regexps], page 120, for how to use the compiled regular expression for matching.)

There is a special data type for compiled regular expressions:

regex_t Data Type

This type of object holds a compiled regular expression. It is actually a structure. It has just one field that your programs should look at:

re_nsub This field holds the number of parenthetical subexpressions in the regular expression that was compiled.

There are several other fields, but we don't describe them here, because only the functions in the library should use them.

After you create a regex_t object, you can compile a regular expression into it by calling regcomp.

int regcomp (regex_t *compiled, const char *pattern, int cflags) Function

The function regcomp "compiles" a regular expression into a data structure that you
can use with regexec to match against a string. The compiled regular expression
format is designed for efficient matching. regcomp stores it into *compiled.

It's up to you to allocate an object of type regex_t and pass its address to regcomp.

The argument *cflags* lets you specify various options that control the syntax and semantics of regular expressions. See Section 9.3.2 [Flags for POSIX Regexps], page 120.

If you use the flag REG_NOSUB, then regcomp omits from the compiled regular expression the information necessary to record how subexpressions actually match. In this case, you might as well pass 0 for the *matchptr* and *nmatch* arguments when you call regexec.

If you don't use REG_NOSUB, then the compiled regular expression does have the capacity to record how subexpressions match. Also, regcomp tells you how many subexpressions pattern has, by storing the number in compiled->re_nsub. You can use that value to decide how long an array to allocate to hold information about subexpression matches.

regcomp returns 0 if it succeeds in compiling the regular expression; otherwise, it returns a nonzero error code (see the table below). You can use regerror to produce an error message string describing the reason for a nonzero value; see Section 9.3.6 [Regexp Cleanup], page 123.

Here are the possible nonzero values that regcomp can return:

REG_BADBR

There was an invalid $\{\ldots\}$ construct in the regular expression. A valid $\{\ldots\}$ construct must contain either a single number, or two numbers in increasing order separated by a comma.

REG_BADPAT

There was a syntax error in the regular expression.

REG_BADRPT

A repetition operator such as '?' or '*' appeared in a bad position (with no preceding subexpression to act on).

REG_ECOLLATE

The regular expression referred to an invalid collating element (one not defined in the current locale for string collation). See Section 7.3 [Locale Categories], page 98.

REG_ECTYPE

The regular expression referred to an invalid character class name.

REG_EESCAPE

The regular expression ended with '\'.

REG_ESUBREG

There was an invalid number in the ' \digit ' construct.

REG_EBRACK

There were unbalanced square brackets in the regular expression.

REG_EPAREN

An extended regular expression had unbalanced parentheses, or a basic regular expression had unbalanced '\(' and '\)'.

REG_EBRACE

The regular expression had unbalanced '\{' and '\}'.

REG_ERANGE

120

One of the endpoints in a range expression was invalid.

REG_ESPACE

regcomp or regexec ran out of memory.

9.3.2 Flags for POSIX Regular Expressions

These are the bit flags that you can use in the *cflags* operand when compiling a regular expression with regcomp.

REG_EXTENDED

Treat the pattern as an extended regular expression, rather than as a basic regular expression.

REG_ICASE

Ignore case when matching letters.

REG_NOSUB

Don't bother storing the contents of the matches_ptr array.

REG_NEWLINE

Treat a newline in *string* as dividing *string* into multiple lines, so that '\$' can match before the newline and '^' can match after. Also, don't permit '.' to match a newline, and don't permit '[^...]' to match a newline.

Otherwise, newline acts like any other ordinary character.

9.3.3 Matching a Compiled POSIX Regular Expression

Once you have compiled a regular expression, as described in Section 9.3.1 [POSIX Regexp Compilation], page 118, you can match it against strings using regexec. A match anywhere inside the string counts as success, unless the regular expression contains anchor characters ('^' or '\$').

This function tries to match the compiled regular expression *compiled against string.

regexec returns 0 if the regular expression matches; otherwise, it returns a nonzero value. See the table below for what nonzero values mean. You can use regerror

to produce an error message string describing the reason for a nonzero value; see Section 9.3.6 [Regexp Cleanup], page 123.

The argument eflags is a word of bit flags that enable various options.

If you want to get information about what part of *string* actually matched the regular expression or its subexpressions, use the arguments *matchptr* and *nmatch*. Otherwise, pass 0 for *nmatch*, and NULL for *matchptr*. See Section 9.3.4 [Regexp Subexpressions], page 121.

You must match the regular expression with the same set of current locales that were in effect when you compiled the regular expression.

The function regexec accepts the following flags in the eflags argument:

REG_NOTBOL

Do not regard the beginning of the specified string as the beginning of a line; more generally, don't make any assumptions about what text might precede it.

REG_NOTEOL

Do not regard the end of the specified string as the end of a line; more generally, don't make any assumptions about what text might follow it.

Here are the possible nonzero values that regexec can return:

REG_NOMATCH

The pattern didn't match the string. This isn't really an error.

REG_ESPACE

regcomp or regexec ran out of memory.

9.3.4 Subexpressions Match Results

When regexec matches parenthetical subexpressions of pattern, it records which parts of string they match. It returns that information by storing the offsets into an array whose elements are structures of type regmatch_t. The first element of the array records the part of the string that matched the entire regular expression. Each other element of the array records the beginning and end of the part that matched a single parenthetical subexpression.

regmatch_t Data Type

This is the data type of the *matcharray* array that you pass to regexec. It contains two structure fields, as follows:

rm_so The offset in *string* of the beginning of a substring. Add this value to *string* to get the address of that part.

rm_eo The offset in string of the end of the substring.

regoff_t Data Type

regoff_t is an alias for another signed integer type. The fields of regmatch_t have type regoff_t.

The regmatch_t elements correspond to subexpressions positionally; the first element records where the first subexpression matched, the second element records the second subexpression, and so on. The order of the subexpressions is the order in which they begin.

When you call regexec, you specify how long the *matchptr* array is, with the *nmatch* argument. This tells regexec how many elements to store. If the actual regular expression has more than *nmatch* subexpressions, then you won't get offset information about the rest of them. But this doesn't alter whether the pattern matches a particular string or not.

If you don't want regexec to return any information about where the subexpressions matched, you can either supply 0 for *nmatch*, or use the flag REG_NOSUB when you compile the pattern with regcomp.

9.3.5 Complications in Subexpression Matching

Sometimes a subexpression matches a substring of no characters. This happens when 'f\(o*\)' matches the string 'fum'. (It really matches just the 'f'.) In this case, both of the offsets identify the point in the string where the null substring was found. In this example, the offsets are both 1.

Sometimes the entire regular expression can match without using some of its subexpressions at all—for example, when 'ba\(na\)*' matches the string 'ba', the parenthetical subexpression is not used. When this happens, regexec stores -1 in both fields of the element for that subexpression.

Sometimes matching the entire regular expression can match a particular subexpression more than once—for example, when 'ba\(na\)*' matches the string 'bananana', the parenthetical subexpression matches three times. When this happens, regexec usually stores the offsets of the last part of the string that matched the subexpression. In the case of 'bananana', these offsets are 6 and 8.

But the last match is not always the one that is chosen. It's more accurate to say that the last opportunity to match is the one that takes precedence. What this means is that when one subexpression appears within another, then the results reported for the inner subexpression reflect whatever happened on the last match of the outer subexpression. For an example, consider '\(ba\(na\)*s\)' matching the string 'bananas bas'. The last time the inner expression actually matches is near the end of the first word. But it is considered again in the second word, and fails to match there. regexec reports nonuse of the "na" subexpression.

Another place where this rule applies is when '\(ba\(na\)*s \|nefer\(ti\)**' matches 'bananas nefertiti'. The "na" subexpression does match in the first word, but it doesn't match in the second word because the other alternative is used there. Once again, the second repetition of the outer subexpression overrides the first, and within that second repetition, the "na" subexpression is not used. So regexec reports nonuse of the "na" subexpression.

9.3.6 POSIX Regexp Matching Cleanup

When you are finished using a compiled regular expression, you can free the storage it uses by calling regfree.

void regfree (regex_t *compiled)

Function

Calling regfree frees all the storage that *compiled points to. This includes various internal fields of the regex_t structure that aren't documented in this manual.

regfree does not free the object *compiled itself.

You should always free the space in a regex_t structure with regfree before using the structure to compile another regular expression.

When regcomp or regexec reports an error, you can use the function regerror to turn it into an error message string.

This function produces an error message string for the error code errcode, and stores the string in length bytes of memory starting at buffer. For the compiled argument, supply the same compiled regular expression structure that regcomp or regexec was working with when it got the error. Alternatively, you can supply NULL for compiled; you will still get a meaningful error message, but it might not be as detailed.

If the error message can't fit in *length* bytes (including a terminating null character), then regerror truncates it. The string that regerror stores is always null-terminated even if it has been truncated.

The return value of regerror is the minimum length needed to store the entire error message. If this is less than *length*, then the error message was not truncated, and you can use it. Otherwise, you should call regerror again with a larger buffer.

```
char *get_regerror (int errcode, regex_t *compiled)
{
    size_t length = regerror (errcode, compiled, NULL, 0);
    char *buffer = xmalloc (length);
    (void) regerror (errcode, compiled, buffer, length);
    return buffer;
}
```

9.4 Shell-Style Word Expansion

Word expansion means the process of splitting a string into words and substituting for variables, commands, and wildcards just as the shell does.

For example, when you write 'ls -l foo.c', this string is split into three separate words—'ls', '-l' and 'foo.c'. This is the most basic function of word expansion.

When you write '1s *.c', this can become many words, because the word '*.c' can be replaced with any number of file names. This is called *wildcard expansion*, and it is also a part of word expansion.

When you use 'echo \$PATH' to print your path, you are taking advantage of variable substitution, which is also part of word expansion.

Ordinary programs can perform word expansion just like the shell by calling the library function wordexp.

9.4.1 The Stages of Word Expansion

When word expansion is applied to a sequence of words, it performs the following transformations in the order shown here:

- 1. Tilde expansion: Replacement of '~foo' with the name of the home directory of 'foo'.
- 2. Next, three different transformations are applied in the same step, from left to right:
 - Variable substitution: The substitution of environment variables for references such as '\$foo'.
 - Command substitution: Replacement of constructs such as "cat foo" or "\$(cat foo)" with the output from the inner command.
 - Arithmetic expansion: Replacement of constructs such as '\$((\$x-1))' with the result of the arithmetic computation.
- 3. Field splitting: subdivision of the text into words.
- 4. Wildcard expansion: The replacement of a construct such as '*.c' with a list of '.c' file names. Wildcard expansion applies to an entire word at a time, and replaces that word with 0 or more file names that are themselves words.
- 5. Quote removal: The deletion of string-quotes, now that they have done their job by inhibiting the above transformations when appropriate.

For the details of these transformations, and how to write the constructs that use them, see *The BASH Manual* (to appear).

9.4.2 Calling wordexp

All the functions, constants and data types for word expansion are declared in the header file 'wordexp.h'.

Word expansion produces a vector of words (strings). To return this vector, wordexp uses a special data type, wordexp_t, which is a structure. You pass wordexp the address of the structure, and it fills in the structure's fields to tell you about the results.

wordexp_t Data Type

This data type holds a pointer to a word vector. More precisely, it records both the address of the word vector and its size.

we_wordc The number of elements in the vector.

we_wordv The address of the vector. This field has type char **.

we_offs The offset of the first real element of the vector, from its nominal address in the we_wordv field. Unlike the other fields, this is always an input to wordexp, rather than an output from it.

If you use a nonzero offset, then that many elements at the beginning of the vector are left empty. (The wordexp function fills them with null pointers.)

The we_offs field is meaningful only if you use the WRDE_DOOFFS flag. Otherwise, the offset is always zero regardless of what is in this field, and the first real element comes at the beginning of the vector.

Perform word expansion on the string words, putting the result in a newly allocated vector, and store the size and address of this vector into *word-vector-ptr. The argument flags is a combination of bit flags; see Section 9.4.3 [Flags for Wordexp], page 127, for details of the flags.

You shouldn't use any of the characters '&;<>' in the string words unless they are quoted; likewise for newline. If you use these characters unquoted, you will get the WRDE_BADCHAR error code. Don't use parentheses or braces unless they are quoted or part of a word expansion construct. If you use quotation characters '''', they should come in pairs that balance.

The results of word expansion are a sequence of words. The function wordexp allocates a string for each resulting word, then allocates a vector of type char ** to store the addresses of these strings. The last element of the vector is a null pointer. This vector is called the word vector.

To return this vector, wordexp stores both its address and its length (number of elements, not counting the terminating null pointer) into *word-vector-ptr.

If wordexp succeeds, it returns 0. Otherwise, it returns one of these error codes:

WRDE_BADCHAR

The input string words contains an unquoted invalid character such as '|'.

WRDE_BADVAL

The input string refers to an undefined shell variable, and you used the flag WRDE_UNDEF to forbid such references.

WRDE_CMDSUB

The input string uses command substitution, and you used the flag WRDE_NOCMD to forbid command substitution.

WRDE_NOSPACE

It was impossible to allocate memory to hold the result. In this case, wordexp can store part of the results—as much as it could allocate room for.

WRDE_SYNTAX

There was a syntax error in the input string. For example, an unmatched quoting character is a syntax error.

void wordfree (wordexp_t *word-vector-ptr)

Function

Free the storage used for the word-strings and vector that *word-vector-ptr points to. This does not free the structure *word-vector-ptr itself—only the other data it points to.

9.4.3 Flags for Word Expansion

This section describes the flags that you can specify in the flags argument to wordexp. Choose the flags you want, and combine them with the C operator |.

WRDE_APPEND

Append the words from this expansion to the vector of words produced by previous calls to wordexp. This way you can effectively expand several words as if they were concatenated with spaces between them.

In order for appending to work, you must not modify the contents of the word vector structure between calls to wordexp. And, if you set WRDE_DOOFFS in the first call to wordexp, you must also set it when you append to the results.

WRDE_DOOFFS

Leave blank slots at the beginning of the vector of words. The we_offs field says how many slots to leave. The blank slots contain null pointers.

WRDE_NOCMD

Don't do command substitution; if the input requests command substitution, report an error.

WRDE_REUSE

Reuse a word vector made by a previous call to wordexp. Instead of allocating a new vector of words, this call to wordexp will use the vector that already exists (making it larger if necessary).

WRDE_SHOWERR

Do show any error messages printed by commands run by command substitution. More precisely, allow these commands to inherit the standard error output stream of the current process. By default, wordexp gives these commands a standard error stream that discards all output.

WRDE_UNDEF

If the input refers to a shell variable that is not defined, report an error.

9.4.4 wordexp Example

Here is an example of using wordexp to expand several strings and use the results to run a shell command. It also shows the use of WRDE_APPEND to concatenate the expansions and of wordfree to free the space allocated by wordexp.

```
int
expand_and_execute (const char *program, const char *options)
  wordexp_t result;
 pid_t pid
  int status, i;
  /* Expand the string for the program to run. */
  switch (wordexp (program, &result, 0))
    {
    case 0: /* Successful. */
      break;
    case WRDE_NOSPACE:
      /* If the error was WRDE_NOSPACE,
         then perhaps part of the result was allocated. */
      wordfree (&result);
                                  /* Some other error. */
    default:
      return -1;
```

```
/* Expand the strings specified for the arguments. */
  for (i = 0; args[i]; i++)
      if (wordexp (options, &result, WRDE_APPEND))
          wordfree (&result);
          return -1;
    }
 pid = fork ();
  if (pid == 0)
    {
      /* This is the child process. Execute the command. */
      execv (result.we_wordv[0], result.we_wordv);
      exit (EXIT_FAILURE);
    }
  else if (pid < 0)
    /* The fork failed. Report failure. */
    status = -1;
    /* This is the parent process. Wait for the child to complete. */
    if (waitpid (pid, &status, 0) != pid)
      status = -1;
 wordfree (&result);
 return status;
}
```

In practice, since wordexp is executed by running a subshell, it would be faster to do this by concatenating the strings with spaces between them and running that as a shell command using 'sh-c'.

10 Input/Output Overview

Most programs need to do either input (reading data) or output (writing data), or most frequently both, in order to do anything useful. The GNU C library provides such a large selection of input and output functions that the hardest part is often deciding which function is most appropriate!

This chapter introduces concepts and terminology relating to input and output. Other chapters relating to the GNU I/O facilities are:

- Chapter 11 [I/O on Streams], page 139, which covers the high-level functions that operate on streams, including formatted input and output.
- Chapter 12 [Low-Level I/O], page 203, which covers the basic I/O and control functions on file descriptors.
- Chapter 13 [File System Interface], page 233, which covers functions for operating on directories and for manipulating file attributes such as access modes and ownership.
- Chapter 14 [Pipes and FIFOs], page 263, which includes information on the basic interprocess communication facilities.
- Chapter 15 [Sockets], page 269, covering a more complicated interprocess communication facility with support for networking.
- Chapter 16 [Low-Level Terminal Interface], page 321, which covers functions for changing how input and output to terminal or other serial devices are processed.

10.1 Input/Output Concepts

Before you can read or write the contents of a file, you must establish a connection or communications channel to the file. This process is called *opening* the file. You can open a file for reading, writing, or both.

The connection to an open file is represented either as a stream or as a file descriptor. You pass this as an argument to the functions that do the actual read or write operations, to tell them which file to operate on. Certain functions expect streams, and others are designed to operate on file descriptors.

When you have finished reading to or writing from the file, you can terminate the connection by *closing* the file. Once you have closed a stream or file descriptor, you cannot do any more input or output operations on it.

10.1.1 Streams and File Descriptors

When you want to do input or output to a file, you have a choice of two basic mechanisms for representing the connection between your program and the file: file descriptors and streams. File descriptors are represented as objects of type int, while streams are represented as FILE * objects.

File descriptors provide a primitive, low-level interface to input and output operations. Both file descriptors and streams can represent a connection to a device (such as a terminal), or a pipe or socket for communicating with another process, as well as a normal file. But, if you want to do control operations that are specific to a particular kind of device, you must use a file descriptor; there are no facilities to use streams in this way. You must also use file descriptors if your program needs to do input or output in special modes, such as nonblocking (or polled) input (see Section 12.10 [File Status Flags], page 224).

Streams provide a higher-level interface, layered on top of the primitive file descriptor facilities. The stream interface treats all kinds of files pretty much alike—the sole exception being the three styles of buffering that you can choose (see Section 11.17 [Stream Buffering], page 189).

The main advantage of using the stream interface is that the set of functions for performing actual input and output operations (as opposed to control operations) on streams is much richer and more powerful than the corresponding facilities for file descriptors. The file descriptor interface provides only simple functions for transferring blocks of characters, but the stream interface also provides powerful formatted input and output functions (printf and scanf) as well as functions for character- and line-oriented input and output.

Since streams are implemented in terms of file descriptors, you can extract the file descriptor from a stream and perform low-level operations directly on the file descriptor. You can also initially open a connection as a file descriptor and then make a stream associated with that file descriptor.

In general, you should stick with using streams rather than file descriptors, unless there is some specific operation you want to do that can only be done on a file descriptor. If you are a beginning programmer and aren't sure what functions to use, we suggest that you concentrate on the formatted input functions (see Section 11.11 [Formatted Input], page 173) and formatted output functions (see Section 11.9 [Formatted Output], page 150).

If you are concerned about portability of your programs to systems other than GNU, you should also be aware that file descriptors are not as portable as streams. You can expect any system running ANSI C to support streams, but non-GNU systems may not support file descriptors at all, or may

only implement a subset of the GNU functions that operate on file descriptors. Most of the file descriptor functions in the GNU library are included in the POSIX.1 standard, however.

10.1.2 File Position

One of the attributes of an open file is its *file position* that keeps track of where in the file the next character is to be read or written. In the GNU system, the file position is simply an integer representing the number of bytes from the beginning of the file.

The file position is normally set to the beginning of the file when it is opened, and each time a character is read or written, the file position is incremented. In other words, access to the file is normally sequential.

Ordinary files permit read or write operations at any position within the file. Some other kinds of files may also permit this. Files which do permit this are sometimes referred to as random-access files. You can change the file position using the fseek function on a stream (see Section 11.15 [File Positioning], page 186) or the lseek function on a file descriptor (see Section 12.2 [I/O Primitives], page 206). If you try to change the file position on a file that doesn't support random access, you get an error.

Streams and descriptors that are opened for append access are treated specially for output: output to such files is always appended sequentially to the end of the file, regardless of the file position. But, the file position is still used to control where in the file reading is done.

If you think about it, you'll realize that several programs can read a given file at the same time. In order for each program to be able to read the file at its own pace, each program must have its own file pointer, which is not affected by anything the other programs do.

In fact, each opening of a file creates a separate file position. Thus, if you open a file twice even in the same program, you get two streams or descriptors with independent file positions.

By contrast, if you open a descriptor and then duplicate it to get another descriptor, these two descriptors share the same file position: changing the file position of one descriptor will affect the other.

10.2 File Names

In order to open a connection to a file, or to perform other operations such as deleting a file, you need some way to refer to the file. Nearly all files have names that are strings—even files which are actually devices such as tape drives or terminals. These strings are called *file names*. You specify the file name to say which file you want to open or operate on.

This section describes the conventions for file names and how the operating system works with them.

10.2.1 Directories

In order to understand the syntax of file names, you need to understand how the file system is organized into a hierarchy of directories.

A directory is a file that contains information to associate other files with names; these associations are called *links* or directory entries. Sometimes, people speak of "files in a directory", but in reality, a directory only contains pointers to files, not the files themselves.

The name of a file contained in a directory entry is called a *file name component*. In general, a file name consists of a sequence of one or more such components, separated by the slash character ('/'). A file name which is just one component names a file with respect to its directory. A file name with multiple components names a directory, and then a file in that directory, and so on.

Some other documents, such as the POSIX standard, use the term pathname for what we call a file name, and either filename or pathname component for what this manual calls a file name component. We don't use this terminology because a "path" is something completely different (a list of directories to search), and we think that "pathname" used for something else will confuse users. We always use "file name" and "file name component" (or sometimes just "component", where the context is obvious) in GNU documentation.

You can find more detailed information about operations on directories in Chapter 13 [File System Interface], page 233.

10.2.2 File Name Resolution

A file name consists of file name components separated by slash ('/') characters. On the systems that that GNU library supports, multiple successive '/' characters are equivalent to a single '/' character.

The process of determining what file a file name refers to is called *file name resolution*. This is performed by examining the components that make up a file name in left-to-right order, and locating each successive component in the directory named by the previous component. Of course, each of the files that are referenced as directories must actually exist, be directories instead of regular files, and have the appropriate permissions to be accessible by the process; otherwise the file name resolution fails.

If a file name begins with a '/', the first component in the file name is located in the root directory of the process. Such a file name is called an absolute file name.

Otherwise, the first component in the file name is located in the current working directory (see Section 13.1 [Working Directory], page 233). This kind of file name is called a *relative file name*.

The file name components '.' ("dot") and '..' ("dot-dot") have special meanings. Every directory has entries for these file name components. The file name component '.' refers to the directory itself, while the file name component '..' refers to its *parent directory* (the directory that contains the link for the directory in question).

Here are some examples of file names:

'/a' The file named 'a', in the root directory.

'/a/b' The file named 'b', in the directory named 'a' in the root directory.

'a' The file named 'a', in the current working directory.

'/a/./b' This is the same as '/a/b'.

'./a' The file named 'a', in the current working directory.

'../a' The file named 'a', in the parent directory of the current working directory.

A file name that names a directory may optionally end in a '/'. You can specify a file name of '/' to refer to the root directory, but the empty string is not a meaningful file name. If you want to refer to the current working directory, use a file name of '.' or './'.

Unlike some other operating systems, the GNU system doesn't have any built-in support for file types (or extensions) or file versions as part of its file name syntax. Many programs and utilities use conventions for file names—for example, files containing C source code usually have names suffixed with '.c'—but there is nothing in the file system itself that enforces this kind of convention.

10.2.3 File Name Errors

Functions that accept file name arguments usually detect these error conditions relating to file name syntax. These errors are referred to throughout this manual as the usual file name syntax errors.

EACCES The process does not have search permission for a directory component of the file name. **ENAMETOOLONG**

This error is used when either the total length of a file name is greater than PATH_MAX, or when an individual file name component has a length greater than NAME_MAX. See Section 27.6 [Limits for Files], page 553.

In the GNU system, there is no imposed limit on overall file name length, but some file systems may place limits on the length of a component.

ENOENT This error is reported when a file referenced as a directory component in the file name doesn't exist.

ENOTDIR A file that is referenced as a directory component in the file name exists, but it isn't a directory.

10.2.4 Portability of File Names

The rules for the syntax of file names discussed in Section 10.2 [File Names], page 134, are the rules normally used by the GNU system and by other POSIX systems. However, other operating systems may use other conventions.

There are two reasons why it can be important for you to be aware of file name portability issues:

• If your program makes assumptions about file name syntax, or contains embedded literal file name strings, it is more difficult to get it to run under other operating systems that use different syntax conventions.

• Even if you are not concerned about running your program on machines that run other operating systems, it may still be possible to access files that use different naming conventions. For example, you may be able to access file systems on another computer running a different operating system over a network, or read and write disks in formats used by other operating systems.

The ANSI C standard says very little about file name syntax, only that file names are strings. In addition to varying restrictions on the length of file names and what characters can validly appear in a file name, different operating systems use different conventions and syntax for concepts such as structured directories and file types or extensions. Some concepts such as file versions might be supported in some operating systems and not by others.

The POSIX.1 standard allows implementations to put additional restrictions on file name syntax, concerning what characters are permitted in file names and on the length of file name and file name component strings. However, in the GNU system, you do not need to worry about these restrictions; any character except the null character is permitted in a file name string, and there are no limits on the length of file name strings.

11 Input/Output on Streams

This chapter describes the functions for creating streams and performing input and output operations on them. As discussed in Chapter 10 [I/O Overview], page 131, a stream is a fairly abstract, high-level concept representing a communications channel to a file, device, or process.

11.1 Streams

For historical reasons, the type of the C data structure that represents a stream is called FILE rather than "stream". Since most of the library functions deal with objects of type FILE *, sometimes the term file pointer is also used to mean "stream". This leads to unfortunate confusion over terminology in many books on C. This manual, however, is careful to use the terms "file" and "stream" only in the technical sense.

The FILE type is declared in the header file 'stdio.h'.

FILE Data Type

This is the data type is used to represent stream objects. A FILE object holds all of the internal state information about the connection to the associated file, including such things as the file position indicator and buffering information. Each stream also has error and end-of-file status indicators that can be tested with the ferror and feof functions; see Section 11.13 [EOF and Errors], page 184.

FILE objects are allocated and managed internally by the input/output library functions. Don't try to create your own objects of type FILE; let the library do it. Your programs should deal only with pointers to these objects (that is, FILE * values) rather than the objects themselves.

11.2 Standard Streams

When the main function of your program is invoked, it already has three predefined streams open and available for use. These represent the "standard" input and output channels that have been established for the process.

These streams are declared in the header file 'stdio.h'.

FILE * stdin Macro

The standard input stream, which is the normal source of input for the program.

FILE * stdout Macro

The standard output stream, which is used for normal output from the program.

FILE * stderr Macro

The standard error stream, which is used for error messages and diagnostics issued by the program.

In the GNU system, you can specify what files or processes correspond to these streams using the pipe and redirection facilities provided by the shell. (The primitives shells use to implement these facilities are described in Chapter 13 [File System Interface], page 233.) Most other operating systems provide similar mechanisms, but the details of how to use them can vary.

It is probably not a good idea to close any of the standard streams. But you can use freopen to get te effect of closing one and reopening it. See Section 11.3 [Opening Streams], page 140.

11.3 Opening Streams

Opening a file with the fopen function creates a new stream and establishes a connection between the stream and a file. This may involve creating a new file.

Everything described in this section is declared in the header file 'stdio.h'.

FILE * fopen (const char *filename, const char *opentype) Function

The fopen function opens a stream for I/O to the file *filename*, and returns a pointer to the stream.

The *opentype* argument is a string that controls how the file is opened and specifies attributes of the resulting stream. It must begin with one of the following sequences of characters:

'r' Open an existing file for reading only.

- 'w' Open the file for writing only. If the file already exists, it is truncated to zero length. Otherwise a new file is created.
- 'a' Open file for append access; that is, writing at the end of file only. If the file already exists, its initial contents are unchanged and output to the stream is appended to the end of the file. Otherwise, a new, empty file is created.
- 'r+' Open existing file for both reading and writing. The initial contents of the file are unchanged and the initial file position is at the beginning of the file.
- 'w+' Open file for both reading and writing. If the file already exists, it is truncated to zero length. Otherwise, a new file is created.
- 'a+' Open or create file for both reading and appending. If the file exists, its initial contents are unchanged. Otherwise, a new file is created. The initial file position for reading might be at either the beginning or end of the file, but output is always appended to the end of the file.

As you can see, '+' requests a stream that can do both input and output. When using such a stream, you must call fflush (see Section 11.17 [Stream Buffering], page 189) or a file positioning function such as fseek (see Section 11.15 [File Positioning], page 186) when switching from reading to writing or vice versa. Otherwise, internal buffers might not be emptied properly.

The GNU C library defines one additional character for use in *opentype*: the character 'x' insists on creating a new file—if a file *filename* already exists, **fopen** fails rather than opening it. This is equivalent to the **O_EXCL** option to the **open** function (see Section 12.10 [File Status Flags], page 224).

The character 'b' in *opentype* has a standard meaning; it requests a binary stream rather than a text stream. But this makes no difference in POSIX systems (including the GNU system). If both '+' and 'b' are specified, they can appear in either order. See Section 11.14 [Binary Streams], page 185.

Any other characters in open type are simply ignored. They may be meaningful in other systems.

If the open fails, fopen returns a null pointer.

You can have multiple streams (or file descriptors) pointing to the same file open at the same time. If you do only input, this works straightforwardly, but you must be careful if any output streams are included. See Section 12.5 [Stream/Descriptor Precautions], page 213. This is equally true whether the streams are in one program (not usual) or in several programs (which can easily happen). It may be advantageous to use the file locking facilities to avoid simultaneous access. See Section 12.11 [File Locks], page 226.

int FOPEN_MAX Macro

The value of this macro is an integer constant expression that represents the minimum number of streams that the implementation guarantees can be open simultaneously. The value of this constant is at least eight, which includes the three standard streams stdin, stdout, and stderr.

FILE * freopen (const char *filename, const char *opentype, FILE *stream)

This function is like a combination of fclose and fopen. It first closes the stream referred to by stream, ignoring any errors that are detected in the process. (Because errors are ignored, you should not use freopen on an output stream if you have actually done any output using the stream.) Then the file named by filename is opened with mode opentype as for fopen, and associated with the same stream object stream.

If the operation fails, a null pointer is returned; otherwise, freopen returns stream.

The main use of freopen is to connect a standard stream such as stdir with a file of your own choice. This is useful in programs in which use of a standard stream for certain purposes is hard-coded.

11.4 Closing Streams

When a stream is closed with fclose, the connection between the stream and the file is cancelled. After you have closed a stream, you cannot perform any additional operations on it any more.

int fclose (FILE *stream)

Function

This function causes *stream* to be closed and the connection to the corresponding file to be broken. Any buffered output is written and any buffered input is discarded. The fclose function returns a value of 0 if the file was closed successfully, and EOF if an error was detected.

It is important to check for errors when you call fclose to close an output stream, because real, everyday errors can be detected at this time. For example, when fclose writes the remaining buffered output, it might get an error because the disk is full. Even if you you know the buffer is empty, errors can still occur when closing a file if you are using NFS.

The function fclose is declared in 'stdio.h'.

If the main function to your program returns, or if you call the exit function (see Section 22.3.1 [Normal Termination], page 476), all open streams are automatically closed properly. If your program terminates in any other manner, such as by calling the abort function (see Section 22.3.4 [Aborting a Program], page 479) or from a fatal signal (see Chapter 21 [Signal Handling], page 403), open streams might not be closed properly. Buffered output may not be flushed and files may not be complete. For more information on buffering of streams, see Section 11.17 [Stream Buffering], page 189.

11.5 Simple Output by Characters or Lines

This section describes functions for performing character- and line-oriented output. Largely for historical compatibility, there are several variants of these functions, but as a matter of style (and for simplicity!) we suggest you stick with using fputc and fputs, and perhaps putc and putchar.

These functions are declared in the header file 'stdio.h'.

int fputc (int c, FILE *stream)

Function

The fputc function converts the character c to type unsigned char, and writes it to the stream stream. EOF is returned if a write error occurs; otherwise the character c is returned.

int putc (int c, FILE *stream)

Function

This is just like fputc, except that most systems implement it as a macro, making it faster. One consequence is that it may evaluate the *stream* argument more than once.

int putchar (int c)

Function

The putchar function is equivalent to fputc with stdout as the value of the stream argument.

int fputs (const char *s, FILE *stream)

Function

The function fputs writes the string s to the stream stream. The terminating null character is not written. This function does not add a newline character, either. It outputs only the chars in the string.

This function returns EOF if a write error occurs, and otherwise a non-negative value.

For example:

```
fputs ("Are ", stdout);
fputs ("you ", stdout);
fputs ("hungry?\n", stdout);
```

outputs the text 'Are you hungry?' followed by a newline.

int puts (const char *s)

Function

The puts function writes the string s to the stream stdout followed by a newline. The terminating null character of the string is not written.

int putw (int w, FILE *stream)

Function

This function writes the word w (that is, an int) to stream. It is provided for compatibility with SVID, but we recommend you use fwrite instead (see Section 11.12 [Block Input/Output], page 183).

11.6 Character Input

This section describes functions for performing character- and line-oriented input. Again, there are several variants of these functions, some of which are considered obsolete stylistically. It's suggested that you stick with fgetc, getline, and maybe getc, getchar and fgets.

These functions are declared in the header file 'stdio.h'.

int fgetc (FILE *stream)

Function

This function reads the next character as an unsigned char from the stream stream and returns its value, converted to an int. If an end-of-file condition or read error occurs, EOF is returned instead.

```
int getc (FILE *stream)
```

Function

This is just like fgetc, except that it is permissible (and typical) for it to be implemented as a macro that evaluates the *stream* argument more than once.

```
int getchar (void)
```

Function

The getchar function is equivalent to fgetc with stdin as the value of the stream argument.

Here is an example of a function that does input using fgetc. It would work just as well using getc instead, or using getchar () instead of fgetc (stdin).

```
int
y_or_n_p (const char *question)
  fputs (question, stdout);
  while (1) {
    int c, answer;
    /* Write a space to separate answer from question. */
    fputc (' ', stdout);
    /* Read the first character of the line.
       This should be the answer character, but might not be. */
    c = tolower (fgetc (stdin));
    answer = c;
    /* Discard rest of input line. */
    while (c != '\n')
      c = fgetc (stdin);
    /* Obey the answer if it was valid. */
    if (answer == 'y')
      return 1;
    if (answer == 'n')
      return 0;
    /* Answer was invalid: ask for valid answer. */
    fputs ("Please answer y or n:", stdout);
}
```

int getw (FILE *stream)

Function

This function reads a word (that is, an int) from stream. It's provided for compatibility with SVID. We recommend you use fread instead (see Section 11.12 [Block Input/Output], page 183).

146 The GNU C Library

11.7 Line-Oriented Input

Since many programs interpret input on the basis of lines, it's convenient to have functions to read a line of text from a stream.

Standard C has functions to do this, but they aren't very safe: null characters and even (for gets) long lines can confuse them. So the GNU library provides the nonstandard getline function that makes it easy to read lines reliably.

Another GNU extension, getdelim, generalizes getline. It reads a delimited record, defined as everything through the next occurrence of a specified delimeter character.

All these functions are declared in 'stdio.h'.

ssize_t getline (char **lineptr, size_t *n, FILE *stream) Function

This function reads an entire line from *stream*, storing the text (including the newline and a terminating null character) in a buffer and storing the buffer address in *lineptr.

Before calling getline, you should place in *lineptr the address of a buffer *n bytes long. If this buffer is long enough to hold the line, getline stores the line in this buffer. Otherwise, getline makes the buffer bigger using realloc, storing the new buffer address back in *lineptr and the increased size back in *n.

In either case, when getline returns, *lineptr is a char * which points to the text of the line.

When getline is successful, it returns the number of characters read (including the newline, but not including the terminating null). This value enables you to distinguish null characters that are part of the line from the null character inserted as a terminator.

This function is a GNU extension, but it is the recommended way to read lines from a stream. The alternative standard functions are unreliable.

If an error occurs or end of file is reached, getline returns -1.

This function is like **getline** except that the character which tells it to stop reading is not necessarily newline. The argument *delimeter* specifies the delimeter character; **getdelim** keeps reading until it sees that character (or end of file).

The text is stored in *lineptr*, including the delimeter character and a terminating null. Like getline, getdelim makes *lineptr* bigger if it isn't big enough.

char * fgets (char *s, int count, FILE *stream)

Function

The fgets function reads characters from the stream stream up to and including a newline character and stores them in the string s, adding a null character to mark the end of the string. You must supply count characters worth of space in s, but the number of characters read is at most count - 1. The extra character space is used to hold the null character at the end of the string.

If the system is already at end of file when you call fgets, then the contents of the array s are unchanged and a null pointer is returned. A null pointer is also returned if a read error occurs. Otherwise, the return value is the pointer s.

Warning: If the input data has a null character, you can't tell. So don't use fgets unless you know the data cannot contain a null. Don't use it to read files edited by the user because, if the user inserts a null character, you should either handle it properly or print a clear error message. We recommend using getline instead of fgets.

char * gets (char *s)

Deprecated function

The function gets reads characters from the stream stdin up to the next newline character, and stores them in the string s. The newline character is discarded (note that this differs from the behavior of fgets, which copies the newline character into the string).

Warning: The gets function is very dangerous because it provides no protection against overflowing the string s. The GNU library includes it for compatibility only. You should always use fgets or getline instead.

148 The GNU C Library

11.8 Unreading

In parser programs it is often useful to examine the next character in the input stream without removing it from the stream. This is called "peeking ahead" at the input because your program gets a glimpse of the input it will read next.

Using stream I/O, you can peek ahead at input by first reading it and then unreading it (also called *pushing it back* on the stream). Unreading a character makes it available to be input again from the stream, by the next call to **fgetc** or other input function on that stream.

11.8.1 What Unreading Means

Here is a pictorial explanation of unreading. Suppose you have a stream reading a file that contains just six characters, the letters 'foobar'. Suppose you have read three characters so far. The situation looks like this:

so the next input character will be 'b'.

If instead of reading 'b' you unread the letter 'o', you get a situation like this:

so that the next input characters will be 'o' and 'b'.

If you unread '9' instead of 'o', you get this situation:

so that the next input characters will be '9' and 'b'.

11.8.2 Using ungetc To Do Unreading

The function to unread a character is called ungetc, because it reverses the action of fgetc.

```
int ungetc (int c, FILE *stream)
```

Function

The ungetc function pushes back the character c onto the input stream stream. So the next input from stream will read c before anything else.

The character that you push back doesn't have to be the same as the last character that was actually read from the stream. In fact, it isn't necessary to actually read any characters from the stream before unreading them with ungetc! But that is a strange way to write a program; usually ungetc is used only to unread a character that was just read from the same stream.

The GNU C library only supports one character of pushback—in other words, it does not work to call ungetc twice without doing input in between. Other systems might let you push back multiple characters; then reading from the stream retrieves the characters in the reverse order that they were pushed.

Pushing back characters doesn't alter the file; only the internal buffering for the stream is affected. If a file positioning function (such as fseek or rewind; see Section 11.15 [File Positioning], page 186) is called, any pending pushed-back characters are discarded.

Unreading a character on a stream that is at end of file clears the end-of-file indicator for the stream, because it makes the character of input available. Reading that character will set the end-of-file indicator again.

Here is an example showing the use of getc and ungetc to skip over whitespace characters. When this function reaches a non-whitespace character, it unreads that character to be seen again on the next read operation on the stream.

```
#include <stdio.h>
void
skip_whitespace (FILE *stream)
```

```
{
  int c;
  do
    /* No need to check for EOF because it is not
    isspace, and ungetc ignores EOF. */
    c = getc (stream);
  while (isspace (c));
  ungetc (c, stream);
}
```

11.9 Formatted Output

The functions described in this section (printf and related functions) provide a convenient way to perform formatted output. You call printf with a format string or template string that specifies how to format the values of the remaining arguments.

Unless your program is a filter that specifically performs line- or character-oriented processing, using printf or one of the other related functions described in this section is usually the easiest and most concise way to perform output. These functions are especially useful for printing error messages, tables of data, and the like.

11.9.1 Formatted Output Basics

The printf function can be used to print any number of arguments. The template string argument you supply in a call provides information not only about the number of additional arguments, but also about their types and what style should be used for printing them.

Ordinary characters in the template string are simply written to the output stream as-is, while conversion specifications introduced by a '%' character in the template cause subsequent arguments to be formatted and written to the output stream. For example,

produces output like

Processing of 'foo.txt' is 37% finished. Please be patient.

This example shows the use of the '%d' conversion to specify that an int argument should be printed in decimal notation, the '%s' conversion to specify printing of a string argument, and the '%%' conversion to print a literal '%' character.

There are also conversions for printing an integer argument as an unsigned value in octal, decimal, or hexadecimal radix ('%o', '%u', or '%x', respectively); or as a character value ('%c').

Floating-point numbers can be printed in normal, fixed-point notation using the '%f' conversion or in exponential notation using the '%e' conversion. The '%g' conversion uses either '%e' or '%f' format, depending on what is more appropriate for the magnitude of the particular number.

You can control formatting more precisely by writing modifiers between the '%' and the character that indicates which conversion to apply. These slightly alter the ordinary behavior of the conversion. For example, most conversion specifications permit you to specify a minimum field width and a flag indicating whether you want the result left- or right-justified within the field.

The specific flags and modifiers that are permitted and their interpretation vary depending on the particular conversion. They're all described in more detail in the following sections. Don't worry if this all seems excessively complicated at first; you can almost always get reasonable free-format output without using any of the modifiers at all. The modifiers are mostly used to make the output look "prettier" in tables.

11.9.2 Output Conversion Syntax

This section provides details about the precise syntax of conversion specifications that can appear in a printf template string.

Characters in the template string that are not part of a conversion specification are printed as-is to the output stream. Multibyte character sequences (see Chapter 6 [Extended Characters], page 83) are permitted in a template string.

The conversion specifications in a printf template string have the general form:

% flags width [. precision] type conversion

For example, in the conversion specifier '%-10.8ld', the '-' is a flag, '10' specifies the field width, the precision is '8', the letter '1' is a type modifier, and 'd' specifies the conversion style. (This particular type specifier says to print a long int argument in decimal notation, with a minimum of 8 digits left-justified in a field at least 10 characters wide.)

In more detail, output conversion specifications consist of an initial '%' character followed in sequence by:

- Zero or more flag characters that modify the normal behavior of the conversion specification.
- An optional decimal integer specifying the *minimum field width*. If the normal conversion produces fewer characters than this, the field is padded with spaces to the specified width. This is a *minimum* value; if the normal conversion produces more characters than this, the field is *not* truncated. Normally, the output is right-justified within the field.
 - The GNU library's version of printf also allows you to specify a field width of '*'. This means that the next argument in the argument list (before the actual value to be printed) is used as the field width. The value must be an int. Other C library versions may not recognize this syntax.
- An optional *precision* to specify the number of digits to be written for the numeric conversions. If the precision is specified, it consists of a period ('.') followed optionally by a decimal integer (which defaults to zero if omitted).
 - The GNU library's version of printf also allows you to specify a precision of '*'. This means that the next argument in the argument list (before the actual value to be printed) is used as the precision. The value must be an int. If you specify '*' for both the field width and precision, the field width argument precedes the precision argument. Other C library versions may not recognize this syntax.
- An optional type modifier character, which is used to specify the data type of the corresponding argument if it differs from the default type. (For example, the integer conversions assume a type of int, but you can specify 'h', '1', or 'L' for other integer types.)
- A character that specifies the conversion to be applied.

The exact options that are permitted and how they are interpreted vary between the different conversion specifiers. See the descriptions of the individual conversions for information about the particular options that they use.

11.9.3 Table of Output Conversions

Here is a table summarizing what all the different conversions do:

- '%d', '%i' Print an integer as a signed decimal number. See Section 11.9.4 [Integer Conversions], page 154, for details. '%d' and '%i' are synonymous for output, but are different when used with scanf for input (see Section 11.11.3 [Table of Input Conversions], page 176).
- '%o' Print an integer as an unsigned octal number. See Section 11.9.4 [Integer Conversions], page 154, for details.
- '%u' Print an integer as an unsigned decimal number. See Section 11.9.4 [Integer Conversions], page 154, for details.
- '%Z' Print an integer as an unsigned decimal number, assuming it was passed with type size_t. See Section 11.9.4 [Integer Conversions], page 154, for details.
- '%x', '%X' Print an integer as an unsigned hexadecimal number. '%x' uses lower-case letters and '%x' uses upper-case. See Section 11.9.4 [Integer Conversions], page 154, for details.
- '%f' Print a floating-point number in normal (fixed-point) notation. See Section 11.9.5 [Floating-Point Conversions], page 156, for details.
- '%e', '%E' Print a floating-point number in exponential notation. '%e' uses lower-case letters and '%E' uses upper-case. See Section 11.9.5 [Floating-Point Conversions], page 156, for details.
- '%g', '%G' Print a floating-point number in either normal or exponential notation, whichever is more appropriate for its magnitude. '%g' uses lower-case letters and '%G' uses uppercase. See Section 11.9.5 [Floating-Point Conversions], page 156, for details.
- '%c' Print a single character. See Section 11.9.6 [Other Output Conversions], page 157.
- '%s' Print a string. See Section 11.9.6 [Other Output Conversions], page 157.
- '%p' Print the value of a pointer. See Section 11.9.6 [Other Output Conversions], page 157.
- '%n' Get the number of characters printed so far. See Section 11.9.6 [Other Output Conversions], page 157. Note that this conversion specification never produces any output.
- '%m' Print the string corresponding to the value of errno. See Section 11.9.6 [Other Output Conversions], page 157.
- '%' Print a literal '%' character. See Section 11.9.6 [Other Output Conversions], page 157.

If the syntax of a conversion specification is invalid, unpredictable things will happen, so don't do this. If there aren't enough function arguments provided to supply values for all the conversion specifications in the template string, or if the arguments are not of the correct types, the results are unpredictable. If you supply more arguments than conversion specifications, the extra argument values are simply ignored; this is sometimes useful.

154 The GNU C Library

11.9.4 Integer Conversions

This section describes the options for the '%d', '%i', '%o', '%u', '%x', '%x', and '%Z' conversion specifications. These conversions print integers in various formats.

The '%d' and '%i' conversion specifications both print an int argument as a signed decimal number; while '%o', '%u', and '%x' print the argument as an unsigned octal, decimal, or hexadecimal number (respectively). The '%x' conversion specification is just like '%x' except that it uses the characters 'ABCDEF' as digits instead of 'abcdef'. '%Z' is like '%u' but expects an argument of type size_t.

The following flags are meaningful:

- '-' Left-justify the result in the field (instead of the normal right-justification).
- '+' For the signed '%d' and '%i' conversions, print a plus sign if the value is positive.
- For the signed '%d' and '%i' conversions, if the result doesn't start with a plus or minus sign, prefix it with a space character instead. Since the '+' flag ensures that the result includes a sign, this flag is ignored if you supply both of them.
- '#' For the '%o' conversion, this forces the leading digit to be '0', as if by increasing the precision. For '%x' or '%x', this prefixes a leading '0x' or '0x' (respectively) to the result. This doesn't do anything useful for the '%d', '%i', or '%u' conversions.
- '0' Pad the field with zeros instead of spaces. The zeros are placed after any indication of sign or base. This flag is ignored if the '-' flag is also specified, or if a precision is specified.

If a precision is supplied, it specifies the minimum number of digits to appear; leading zeros are produced if necessary. If you don't specify a precision, the number is printed with as many digits as it needs. If you convert a value of zero with an explicit precision of zero, then no characters at all are produced.

Without a type modifier, the corresponding argument is treated as an int (for the signed conversions '%i' and '%d') or unsigned int (for the unsigned conversions '%o', '%u', '%x', and '%X'). Recall that since printf and friends are variadic, any char and short arguments are automatically converted to int by the default argument promotions. For arguments of other integer types, you can use these modifiers:

- 'h' Specifies that the argument is a short int or unsigned short int, as appropriate.

 A short argument is converted to an int or unsigned int by the default argument promotions anyway, but the 'h' modifier says to convert it back to a short again.
- '1' Specifies that the argument is a long int or unsigned long int, as appropriate.
- 'L' Specifies that the argument is a long long int. (This type is an extension supported by the GNU C compiler. On systems that don't support extra-long integers, this is the same as long int.)

The modifiers for argument type are not applicable to '%Z', since the sole purpose of '%Z' is to specify the data type size_t.

Here is an example. Using the template string:

```
|\%5d|\%-5d|\%+5d|\%+-5d|\% 5d|\%05d|\%5.0d|\%5.2d|\%d|\n''
```

to print numbers using the different options for the '%d' conversion gives results like:

In particular, notice what happens in the last case where the number is too large to fit in the minimum field width specified.

Here are some more examples showing how unsigned integers print under various format options, using the template string:

```
"|%5u|%5o|%5x|%5X|%#5o|%#5x|%#5X|%#10.8x|\n"
```

156 The GNU C Library

11.9.5 Floating-Point Conversions

This section discusses the conversion specifications for floating-point numbers: the '%f', '%e', '%E', '%g', and '%G' conversions.

The '%f' conversion prints its argument in fixed-point notation, producing output of the form [-]ddd.ddd, where the number of digits following the decimal point is controlled by the precision you specify.

The '%e' conversion prints its argument in exponential notation, producing output of the form [-]d.ddde[+|-]dd. Again, the number of digits following the decimal point is controlled by the precision. The exponent always contains at least two digits. The '%E' conversion is similar but the exponent is marked with the letter 'E' instead of 'e'.

The '%g' and '%G' conversions print the argument in the style of '%e' or '%E' (respectively) if the exponent would be less than -4 or greater than or equal to the precision; otherwise they use the '%f' style. Trailing zeros are removed from the fractional portion of the result and a decimal-point character appears only if it is followed by a digit.

The following flags can be used to modify the behavior:

- '-' Left-justify the result in the field. Normally the result is right-justified.
- '+' Always include a plus or minus sign in the result.
- '' If the result doesn't start with a plus or minus sign, prefix it with a space instead. Since the '+' flag ensures that the result includes a sign, this flag is ignored if you supply both of them.
- '#' Specifies that the result should always include a decimal point, even if no digits follow it. For the '%g' and '%G' conversions, this also forces trailing zeros after the decimal point to be left in place where they would otherwise be removed.
- '0' Pad the field with zeros instead of spaces; the zeros are placed after any sign. This flag is ignored if the '-' flag is also specified.

The precision specifies how many digits follow the decimal-point character for the '%f', '%e', and '%E' conversions. For these conversions, the default is 6. If the precision is explicitly 0, this has the rather strange effect of suppressing the decimal point character entirely! For the '%g' and '%G' conversions, the precision specifies how many significant digits to print; if 0 or not specified, it is treated like a value of 1.

Without a type modifier, the floating-point conversions use an argument of type double. (By the default argument promotions, any float arguments are automatically converted to double.) The following type modifier is supported:

'L' An uppercase 'L' specifies that the argument is a long double.

Here are some examples showing how numbers print using the various floating-point conversions. All of the numbers were printed using this template string:

```
"|%12.4f|%12.4e|%12.4g|n"
```

Here is the output:

```
0.0000
              0.0000e+001
                                     0 |
     1.0000|
              1.0000e+00|
                                     1 |
    -1.0000| -1.0000e+00|
                                     -1|
   100.0000
              1.0000e+02
                                   100
  1000.0000|
                                  1000
              1.0000e+03
 10000.0000
              1.0000e+04
                                 1e+04|
 12345.0000
              1.2345e+04|
                             1.234e+04
100000.0000|
              1.0000e+05|
                                 1e+05|
123456.0000|
              1.2346e+05
                             1.234e+05
```

Notice how the '%g' conversion drops trailing zeros.

11.9.6 Other Output Conversions

This section describes miscellaneous conversions for printf.

The '%c' conversion prints a single character. The int argument is first converted to an unsigned char. The '-' flag can be used to specify left-justification in the field, but no other flags are defined, and no precision or type modifier can be given. For example:

```
printf ("%c%c%c%c", 'h', 'e', 'l', 'l', 'o');
```

158 The GNU C Library

prints 'hello'.

The '%s' conversion prints a string. The corresponding argument must be of type char *. A precision can be specified to indicate the maximum number of characters to write; otherwise characters in the string up to but not including the terminating null character are written to the output stream. The '-' flag can be used to specify left-justification in the field, but no other flags or type modifiers are defined for this conversion. For example:

```
printf ("%3s%-6s", "no", "where");
```

prints 'nowhere'.

If you accidentally pass a null pointer as the argument for a '%s' conversion, the GNU library prints it as '(null)'. We think this is more useful than crashing. But it's not good practice to pass a null argument intentionally.

The '%m' conversion prints the string corresponding to the error code in errno. See Section 2.3 [Error Messages], page 25. Thus:

```
fprintf (stderr, "can't open '%s': %m\n", filename);
```

is equivalent to:

```
fprintf (stderr, "can't open '%s': %s\n", filename, strerror (errno));
```

The '%m' conversion is a GNU C library extension.

The '%p' conversion prints a pointer value. The corresponding argument must be of type void
*. In practice, you can use any type of pointer.

In the GNU system, non-null pointers are printed as unsigned integers, as if a '%#x' conversion were used. Null pointers print as '(nil)'. (Pointers might print differently in other systems.)

For example:

```
printf ("%p", "testing");
```

prints '0x' followed by a hexadecimal number—the address of the string constant "testing". It does not print the word 'testing'.

You can supply the '-' flag with the '%p' conversion to specify left-justification, but no other flags, precision, or type modifiers are defined.

The '%n' conversion is unlike any of the other output conversions. It uses an argument which must be a pointer to an int, but instead of printing anything it stores the number of characters printed so far by this call at that location. The 'h' and '1' type modifiers are permitted to specify that the argument is of type short int * or long int * instead of int *, but no flags, field width, or precision are permitted.

```
For example,
```

```
int nchar;
printf ("%d %s%n\n", 3, "bears", &nchar);
```

prints:

3 bears

and sets nchar to 7, because '3 bears' is seven characters.

The '%%' conversion prints a literal '%' character. This conversion doesn't use an argument, and no flags, field width, precision, or type modifiers are permitted.

11.9.7 Formatted Output Functions

This section describes how to call **printf** and related functions. Prototypes for these functions are in the header file 'stdio.h'.

int printf (const char *template, ...)

Function

The **printf** function prints the optional arguments under the control of the template string *template* to the stream **stdout**. It returns the number of characters printed, or a negative value if there was an output error.

int fprintf (FILE *stream, const char *template, ...)

Function

This function is just like **printf**, except that the output is written to the stream stream instead of **stdout**.

int **sprintf** (char *s, const char *template, ...)

Function

This is like **printf**, except that the output is stored in the character array s instead of written to a stream. A null character is written to mark the end of the string.

The **sprintf** function returns the number of characters stored in the array s, not including the terminating null character.

The behavior of this function is undefined if copying takes place between objects that overlap—for example, if s is also given as an argument to be printed under control of the '%s' conversion. See Section 5.4 [Copying and Concatenation], page 67.

Warning: The sprintf function can be dangerous because it can potentially output more characters than can fit in the allocation size of the string s. Remember that the field width given in a conversion specification is only a minimum value.

To avoid this problem, you can use snprintf or asprintf, described below.

int snprintf (char *s, size_t size, const char *template, ...)

Function

The snprintf function is similar to sprintf, except that the size argument specifies the maximum number of characters to produce. The trailing null character is counted towards this limit, so you should allocate at least size characters for the string s.

The return value is the number of characters stored, not including the terminating null. If this value equals *size*, then there was not enough space in s for all the output. You should try again with a bigger output string. Here is an example of doing this:

```
/* Construct a message describing the value of a variable
   whose name is name and whose value is value. */
char *
make_message (char *name, char *value)
{
  /* Guess we need no more than 100 chars of space. */
  int size = 100;
  char *buffer = (char *) xmalloc (size);
  while (1)
    {
      /* Try to print in the allocated space. */
      int nchars = snprintf (buffer, size,
                                "value of %s is %s", name, value);
      /* If that worked, return the string. */
      if (nchars < size)
        return buffer;
      /* Else try again with twice as much space. */
      size *= 2;
      buffer = (char *) xrealloc (size, buffer);
    }
}
```

In practice, it is often easier just to use asprintf, below.

11.9.8 Dynamically Allocating Formatted Output

The functions in this section do formatted output and place the results in dynamically allocated memory.

```
int asprintf (char **ptr, const char *template, ...) Function
```

This function is similar to sprintf, except that it dynamically allocates a string (as with malloc; see Section 3.3 [Unconstrained Allocation], page 30) to hold the output, instead of putting the output in a buffer you allocate in advance. The *ptr* argument should be the address of a char * object, and asprintf stores a pointer to the newly allocated string at that location.

Here is how to use asprint to get the same result as the snprintf example, but more easily:

```
/* Construct a message describing the value of a variable
   whose name is name and whose value is value. */
char *
make_message (char *name, char *value)
{
   char *result;
   asprintf (&result, "value of %s is %s", name, value);
   return result;
}
```

```
int obstack_printf (struct obstack *obstack, const char *template,
...)
Function
```

This function is similar to asprintf, except that it uses the obstack obstack to allocate the space. See Section 3.4 [Obstacks], page 40.

The characters are written onto the end of the current object. To get at them, you must finish the object with obstack_finish (see Section 3.4.6 [Growing Objects], page 46).

11.9.9 Variable Arguments Output Functions

The functions vprintf and friends are provided so that you can define your own variadic printf-like functions that make use of the same internals as the built-in formatted output functions.

The most natural way to define such functions would be to use a language construct to say, "Call printf and pass this template plus all of my arguments after the first five." But there is no way to do this in C, and it would be hard to provide a way, since at the C language level there is no way to tell how many arguments your function received.

Since that method is impossible, we provide alternative functions, the **vprintf** series, which lets you pass a **va_list** to describe "all of my arguments after the first five."

Before calling vprintf or the other functions listed in this section, you must call va_start (see Section A.2 [Variadic Functions], page 564) to initialize a pointer to the variable arguments. Then you can call va_arg to fetch the arguments that you want to handle yourself. This advances the pointer past those arguments.

Once your va_list pointer is pointing at the argument of your choice, you are ready to call vprintf. That argument and all subsequent arguments that were passed to your function are used by vprintf along with the template that you specified separately.

In some other systems, the va_list pointer may become invalid after the call to vprintf, so you must not use va_arg after you call vprintf. Instead, you should call va_end to retire the pointer from service. However, you can safely call va_start on another pointer variable and begin fetching the arguments again through that pointer. Calling vfprintf does not destroy the argument list of your function, merely the particular pointer that you passed to it.

The GNU library does not have such restrictions. You can safely continue to fetch arguments from a va_list pointer after passing it to vprintf, and va_end is a no-op.

Prototypes for these functions are declared in 'stdio.h'.

int vprintf (const char *template, va_list ap)

Function

This function is similar to **printf** except that, instead of taking a variable number of arguments directly, it takes an argument list pointer ap.

int vfprintf (FILE *stream, const char *template, va_list ap)

Function

This is the equivalent of fprintf with the variable argument list specified directly as for vprintf.

int **vsprintf** (char *s, const char *template, va_list ap)

Function

This is the equivalent of **sprintf** with the variable argument list specified directly as for **vprintf**.

int vsnprintf (char *s, size_t size, const char *template, va_list
ap)

Function

This is the equivalent of **snprintf** with the variable argument list specified directly as for **vprintf**.

int vasprintf (char **ptr, const char *template, va_list ap)

Function

The vasprintf function is the equivalent of asprintf with the variable argument list specified directly as for vprintf.

The obstack_vprintf function is the equivalent of obstack_printf with the variable argument list specified directly as for vprintf.

Here's an example showing how you might use vfprintf. This is a function that prints error messages to the stream stderr, along with a prefix indicating the name of the program (see Section 2.3 [Error Messages], page 25, for a description of program_invocation_short_name).

```
#include <stdio.h>
#include <stdarg.h>

void
eprintf (char *template, ...)
{
    va_list ap;
    extern char *program_invocation_short_name;
    fprintf (stderr, "%s: ", program_invocation_short_name);
    va_start (ap, count);
    vfprintf (stderr, template, ap);
    va_end (ap);
}
```

You could call eprintf like this:

```
eprintf ("file '%s' does not exist\n", filename);
```

11.9.10 Parsing a Template String

You can use the function parse_printf_format to obtain information about the number and types of arguments that are expected by a given template string. This function permits interpreters that provide interfaces to printf to avoid passing along invalid arguments from the user's program, which could cause a crash.

All the symbols described in this section are declared in the header file 'printf.h'.

This function returns information about the number and types of arguments expected by the **printf** template string template. The information is stored in the array argtypes; each element of this array describes one argument. This information is encoded using the various 'PA_' macros, listed below.

The *n* argument specifies the number of elements in the array *argtypes*. This is the most elements that parse_printf_format will try to write.

parse_printf_format returns the total number of arguments required by template. If this number is greater than n, then the information returned describes only the first n arguments. If you want information about more than that many arguments, allocate a bigger array and call parse_printf_format again.

The argument types are encoded as a combination of a basic type and modifier flag bits.

int PA_FLAG_MASK

Macro

This macro is a bitmask for the type modifier flag bits. You can write the expression (argtypes[i] & PA_FLAG_MASK) to extract just the flag bits for an argument, or (argtypes[i] & ~PA_FLAG_MASK) to extract just the basic type code.

Here are symbolic constants that represent the basic types; they stand for integer values.

PA_INT This specifies that the base type is int.

PA_CHAR This specifies that the base type is int, cast to char.

PA_STRING

This specifies that the base type is char *, a null-terminated string.

PA_POINTER

This specifies that the base type is void *, an arbitrary pointer.

PA_FLOAT This specifies that the base type is float.

PA_DOUBLE

This specifies that the base type is double.

PA_LAST You can define additional base types for your own programs as offsets from PA_LAST. For example, if you have data types 'foo' and 'bar' with their own specialized printf conversions, you could define encodings for these types as:

166 The GNU C Library

```
#define PA_FOO PA_LAST
#define PA_BAR (PA_LAST + 1)
```

Here are the flag bits that modify a basic type. They are combined with the code for the basic type using inclusive-or.

PA_FLAG_PTR

If this bit is set, it indicates that the encoded type is a pointer to the base type, rather than an immediate value. For example, 'PA_INT|PA_FLAG_PTR' represents the type 'int *'.

PA_FLAG_SHORT

If this bit is set, it indicates that the base type is modified with short. (This corresponds to the 'h' type modifier.)

PA_FLAG_LONG

If this bit is set, it indicates that the base type is modified with long. (This corresponds to the '1' type modifier.)

PA_FLAG_LONG_LONG

If this bit is set, it indicates that the base type is modified with long long. (This corresponds to the 'L' type modifier.)

PA_FLAG_LONG_DOUBLE

This is a synonym for PA_FLAG_LONG_LONG, used by convention with a base type of PA_DOUBLE to indicate a type of long double.

11.9.11 Example of Parsing a Template String

Here is an example of decoding argument types for a format string. We assume this is part of an interpreter which contains arguments of type NUMBER, CHAR, STRING and STRUCTURE (and perhaps others which are not valid here).

```
/* Test whether the nargs specified objects
  in the vector args are valid
  for the format string format:
  if so, return 1.
   If not, return 0 after printing an error message. */
int
validate_args (char *format, int nargs, OBJECT *args)
```

{

```
int nelts = 20;
int *argtypes;
int nwanted;
/* Get the information about the arguments. */
while (1) {
  argtypes = (int *) alloca (nelts * sizeof (int));
  nwanted = parse_printf_format (string, nelts, argtypes);
  if (nwanted <= nelts)</pre>
    break;
 nelts *= 2;
/* Check the number of arguments. */
if (nwanted > nargs) {
  error ("too few arguments (at least %d required)", nwanted);
  return 0;
}
/* Check the C type wanted for each argument
   and see if the object given is suitable. */
for (i = 0; i < nwanted; i++) {
  int wanted;
  if (argtypes[i] & PA_FLAG_PTR)
    wanted = STRUCTURE;
  else
    switch (argtypes[i] & ~PA_FLAG_MASK) {
    case PA_INT:
    case PA_FLOAT:
    case PA_DOUBLE:
      wanted = NUMBER;
      break;
    case PA_CHAR:
      wanted = CHAR;
      break;
    case PA_STRING:
      wanted = STRING;
      break;
    case PA_POINTER:
      wanted = STRUCTURE;
      break;
  if (TYPE (args[i]) != wanted) {
    error ("type mismatch for arg number %d", i);
    return 0;
  }
}
return 1;
```

}

11.10 Customizing printf

The GNU C library lets you define your own custom conversion specifiers for printf template strings, to teach printf clever ways to print the important data structures of your program.

The way you do this is by registering the conversion with register_printf_function; see Section 11.10.1 [Registering New Conversions], page 168. One of the arguments you pass to this function is a pointer to a handler function that produces the actual output; see Section 11.10.3 [Defining the Output Handler], page 170, for information on how to write this function.

You can also install a function that just returns information about the number and type of arguments expected by the conversion specifier. See Section 11.9.10 [Parsing a Template String], page 164, for information about this.

The facilities of this section are declared in the header file 'printf.h'.

Portability Note: The ability to extend the syntax of **printf** template strings is a GNU extension. ANSI standard C has nothing similar.

11.10.1 Registering New Conversions

The function to register a new output conversion is register_printf_function, declared in 'printf.h'.

int register_printf_function (int spec, printf_function

Function

handler function, printf_arginfo_function arginfo function)

This function defines the conversion specifier character spec. Thus, if spec is 'q', it defines the conversion '%q'.

The handler_function is the function called by printf and friends when this conversion appears in a template string. See Section 11.10.3 [Defining the Output Handler], page 170, for information about how to define a function to pass as this argument. If you specify a null pointer, any existing handler function for spec is removed.

The arginfo_function is the function called by parse_printf_format when this conversion appears in a template string. See Section 11.9.10 [Parsing a Template String], page 164, for information about this.

Normally, you install both functions for a conversion at the same time, but if you are never going to call parse_printf_format, you do not need to define an arginfo function.

The return value is 0 on success, and -1 on failure (which occurs if spec is out of range).

You can redefine the standard output conversions, but this is probably not a good idea because of the potential for confusion. Library routines written by other people could break if you do this.

11.10.2 Conversion Specifier Options

If you define a meaning for '%q', what if the template contains '%+Sq' or '%-#q'? To implement a sensible meaning for these, the handler when called needs to be able to get the options specified in the template.

Both the handler_function and arginfo_function arguments to register_printf_function accept an argument of type struct print_info, which contains information about the options appearing in an instance of the conversion specifier. This data type is declared in the header file 'printf.h'.

struct printf_info Type

This structure is used to pass information about the options appearing in an instance of a conversion specifier in a **printf** template string to the handler and arginfo functions for that specifier. It contains the following members:

int prec This is the precision specified. The value is -1 if no precision was specified. If the precision was given as '*', the printf_info structure passed to the handler function contains the actual value retrieved from the argument list. But the structure passed to the arginfo function contains a value of INT_MIN, since the actual value is not known.

int width This is the minimum field width specified. The value is 0 if no width was specified. If the field width was given as '*', the printf_info structure

passed to the handler function contains the actual value retrieved from the argument list. But the structure passed to the arginfo function contains a value of INT_MIN, since the actual value is not known.

char spec This is the conversion specifier character specified. It's stored in the structure so that you can register the same handler function for multiple characters, but still have a way to tell them apart when the handler function is called.

unsigned int is_long_double

This is a boolean that is true if the 'L' type modifier was specified.

unsigned int is_short

This is a boolean that is true if the 'h' type modifier was specified.

unsigned int is_long

This is a boolean that is true if the '1' type modifier was specified.

unsigned int alt

This is a boolean that is true if the '#' flag was specified.

unsigned int space

This is a boolean that is true if the ' ' flag was specified.

unsigned int left

This is a boolean that is true if the '-' flag was specified.

unsigned int showsign

This is a boolean that is true if the '+' flag was specified.

char pad This is the character to use for padding the output to the minimum field width. The value is '0' if the '0' flag was specified, and ' ' otherwise.

11.10.3 Defining the Output Handler

Now let's look at how to define the handler and arginfo functions which are passed as arguments to register_printf_function.

You should define your handler functions with a prototype like:

The stream argument passed to the handler function is the stream to which it should write output.

The info argument is a pointer to a structure that contains information about the various options that were included with the conversion in the template string. You should not modify this structure inside your handler function. See Section 11.10.2 [Conversion Specifier Options], page 169, for a description of this data structure.

The ap_pointer argument is used to pass the tail of the variable argument list containing the values to be printed to your handler. Unlike most other functions that can be passed an explicit variable argument list, this is a *pointer* to a va_list, rather than the va_list itself. Thus, you should fetch arguments by means of va_arg (type, *ap_pointer).

(Passing a pointer here allows the function that calls your handler function to update its own va_list variable to account for the arguments that your handler processes. See Section A.2 [Variadic Functions], page 564.)

The return value from your handler function should be the number of argument values that it processes from the variable argument list. You can also return a value of -1 to indicate an error.

printf_function Data Type

This is the data type that a handler function should have.

If you are going to use parse_printf_format in your application, you should also define a function to pass as the arginfo_function argument for each new conversion you install with register_printf_function.

You should define these functions with a prototype like:

The return value from the function should be the number of arguments the conversion expects, up to a maximum of n. The function should also fill in the argtypes array with information about the types of each of these arguments. This information is encoded using the various 'PA_' macros. (You will notice that this is the same calling convention parse_printf_format itself uses.)

printf_arginfo_function

Data Type

This type is used to describe functions that return information about the number and type of arguments used by a conversion specifier.

11.10.4 printf Extension Example

Here is an example showing how to define a printf handler function. This program defines a data structure called a Widget and defines the '%W' conversion to print information about Widget * arguments, including the pointer value and the name stored in the data structure. The '%W' conversion supports the minimum field width and left-justification options, but ignores everything else.

```
#include <stdio.h>
#include <printf.h>
#include <stdarg.h>
typedef struct
  {
    char *name;
  } Widget;
int
print_widget (FILE *stream, const struct printf_info *info, va_list *app)
 Widget *w;
  char *buffer;
  int len;
  /* Format the output into a string. */
 w = va_arg (*app, Widget *);
  len = asprintf (&buffer, "<Widget %p: %s>", w, w->name);
  if (len == -1)
    return -1;
  /* Pad to the minimum field width and print to the stream. */
  len = fprintf (stream, "%*s",
 (info->left ? - info->width : info->width),
 buffer);
  /* Clean up and return. */
 free (buffer);
  return len;
}
```

```
int
main (void)
{
    /* Make a widget to print. */
    Widget mywidget;
    mywidget.name = "mywidget";

    /* Register the print function for widgets. */
    register_printf_function ('W', print_widget, NULL); /* No arginfo. */

    /* Now print the widget. */
    printf ("|%W|\n", &mywidget);
    printf ("|%35W|\n", &mywidget);
    printf ("|%-35W|\n", &mywidget);
    return 0;
}
```

The output produced by this program looks like:

11.11 Formatted Input

The functions described in this section (scanf and related functions) provide facilities for formatted input analogous to the formatted output facilities. These functions provide a mechanism for reading arbitrary values under the control of a format string or template string.

11.11.1 Formatted Input Basics

Calls to scanf are superficially similar to calls to printf in that arbitrary arguments are read under the control of a template string. While the syntax of the conversion specifications in the template is very similar to that for printf, the interpretation of the template is oriented more towards free-format input and simple pattern matching, rather than fixed-field formatting. For example, most scanf conversions skip over any amount of "white space" (including spaces, tabs, and newlines) in the input file, and there is no concept of precision for the numeric input conversions as there is for the corresponding output conversions. Ordinarily, non-whitespace characters in the

template are expected to match characters in the input stream exactly, but a matching failure is distinct from an input error on the stream.

Another area of difference between scanf and printf is that you must remember to supply pointers rather than immediate values as the optional arguments to scanf; the values that are read are stored in the objects that the pointers point to. Even experienced programmers tend to forget this occasionally, so if your program is getting strange errors that seem to be related to scanf, you might want to double-check this.

When a matching failure occurs, scanf returns immediately, leaving the first non-matching character as the next character to be read from the stream. The normal return value from scanf is the number of values that were assigned, so you can use this to determine if a matching error happened before all the expected values were read.

The scanf function is typically used for things like reading in the contents of tables. For example, here is a function that uses scanf to initialize an array of double:

```
void
readarray (double *array, int n)
{
   int i;
   for (i=0; i<n; i++)
      if (scanf (" %lf", &(array[i])) != 1)
      invalid_input_error ();
}</pre>
```

The formatted input functions are not used as frequently as the formatted output functions. Partly, this is because it takes some care to use them properly. Another reason is that it is difficult to recover from a matching error.

If you are trying to read input that doesn't match a single, fixed pattern, you may be better off using a tool such as Bison to generate a parser, rather than using scanf. For more information about this, see section "Bison" in *The Bison Reference Manual*.

11.11.2 Input Conversion Syntax

A scanf template string is a string that contains ordinary multibyte characters interspersed with conversion specifications that start with '%'.

Any whitespace character (as defined by the isspace function; see Section 4.1 [Classification of Characters], page 61) in the template causes any number of whitespace characters in the input stream to be read and discarded. The whitespace characters that are matched need not be exactly the same whitespace characters that appear in the template string. For example, write ',' in the template to recognize a comma with optional whitespace before and after.

Other characters in the template string that are not part of conversion specifications must match characters in the input stream exactly; if this is not the case, a matching failure occurs.

The conversion specifications in a scanf template string have the general form:

% flags width type conversion

In more detail, an input conversion specification consists of an initial '%' character followed in sequence by:

- An optional flag character '*', which says to ignore the text read for this specification. When scanf finds a conversion specification that uses this flag, it reads input as directed by the rest of the conversion specification, but it discards this input, does not use a pointer argument, and does not increment the count of successful assignments.
- An optional flag character 'a' (valid with string conversions only) which requests allocation of a buffer long enough to store the string in. See Section 11.11.6 [Dynamic String Input], page 180.
- An optional decimal integer that specifies the maximum field width. Reading of characters from the input stream stops either when this maximum is reached or when a non-matching character is found, whichever happens first. Most conversions discard initial whitespace characters (those that don't are explicitly documented), and these discarded characters don't count towards the maximum field width. Most input conversions store a null character to mark the end of the input; the maximum field width does not include this terminator.
- An optional type modifier character. For example, you can specify a type modifier of '1' with integer conversions such as '%d' to specify that the argument is a pointer to a long int rather than a pointer to an int.
- A character that specifies the conversion to be applied.

The exact options that are permitted and how they are interpreted vary between the different conversion specifiers. See the descriptions of the individual conversions for information about the particular options that they allow.

11.11.3 Table of Input Conversions

Here is a table that summarizes the various conversion specifications:

- '%d' Matches an optionally signed integer written in decimal. See Section 11.11.4 [Numeric Input Conversions], page 177.
- '%i' Matches an optionally signed integer in any of the formats that the C language defines for specifying an integer constant. See Section 11.11.4 [Numeric Input Conversions], page 177.
- '%o' Matches an unsigned integer in octal radix. See Section 11.11.4 [Numeric Input Conversions], page 177.
- '%u' Matches an unsigned integer in decimal radix. See Section 11.11.4 [Numeric Input Conversions], page 177.
- '%x', '%x' Matches an unsigned integer in hexadecimal radix. See Section 11.11.4 [Numeric Input Conversions], page 177.
- '%e', '%f', '%g', '%E', '%G'
 - Matches an optionally signed floating-point number. See Section 11.11.4 [Numeric Input Conversions], page 177.
- '%s' Matches a string of non-whitespace characters. See Section 11.11.5 [String Input Conversions], page 178.
- '%[' Matches a string of characters that belong to a specified set. See Section 11.11.5 [String Input Conversions], page 178.
- '%c' Matches a string of one or more characters; the number of characters read is controlled by the maximum field width given for the conversion. See Section 11.11.5 [String Input Conversions], page 178.
- '%p' Matches a pointer value in the same implementation-defined format used by the '%p' output conversion for printf. See Section 11.11.7 [Other Input Conversions], page 181.
- '%n' This conversion doesn't read any characters; it records the number of characters read so far by this call. See Section 11.11.7 [Other Input Conversions], page 181.
- '%',' This matches a literal '%' character in the input stream. No corresponding argument is used. See Section 11.11.7 [Other Input Conversions], page 181.

If the syntax of a conversion specification is invalid, the behavior is undefined. If there aren't enough function arguments provided to supply addresses for all the conversion specifications in the template strings that perform assignments, or if the arguments are not of the correct types, the behavior is also undefined. On the other hand, extra arguments are simply ignored.

11.11.4 Numeric Input Conversions

This section describes the scanf conversions for reading numeric values.

The '%d' conversion matches an optionally signed integer in decimal radix. The syntax that is recognized is the same as that for the strtol function (see Section 18.7.1 [Parsing of Integers], page 366) with the value 10 for the base argument.

The '%i' conversion matches an optionally signed integer in any of the formats that the C language defines for specifying an integer constant. The syntax that is recognized is the same as that for the strtol function (see Section 18.7.1 [Parsing of Integers], page 366) with the value 0 for the base argument.

For example, any of the strings '10', '0xa', or '012' could be read in as integers under the '%i' conversion. Each of these specifies a number with decimal value 10.

The '%o', '%u', and '%x' conversions match unsigned integers in octal, decimal, and hexadecimal radices, respectively. The syntax that is recognized is the same as that for the strtoul function (see Section 18.7.1 [Parsing of Integers], page 366) with the appropriate value (8, 10, or 16) for the base argument.

The ' $\mbox{\%}\mbox{X}$ ' conversion is identical to the ' $\mbox{\%}\mbox{x}$ ' conversion. They both permit either uppercase or lowercase letters to be used as digits.

The default type of the corresponding argument for the %d and %i conversions is int *, and unsigned int * for the other integer conversions. You can use the following type modifiers to specify other sizes of integer:

- 'h' Specifies that the argument is a short int * or unsigned short int *.
- '1' Specifies that the argument is a long int * or unsigned long int *.
- 'L' Specifies that the argument is a long long int * or unsigned long long int *. (The long long type is an extension supported by the GNU C compiler. For systems that don't provide extra-long integers, this is the same as long int.)

All of the '%e', '%f', '%g', '%E', and '%G' input conversions are interchangeable. They all match an optionally signed floating point number, in the same syntax as for the strtod function (see Section 18.7.2 [Parsing of Floats], page 368).

For the floating-point input conversions, the default argument type is float *. (This is different from the corresponding output conversions, where the default type is double; remember that float arguments to printf are converted to double by the default argument promotions, but float * arguments are not promoted to double *.) You can specify other sizes of float using these type modifiers:

- '1' Specifies that the argument is of type double *.
- 'L' Specifies that the argument is of type long double *.

11.11.5 String Input Conversions

178

This section describes the **scanf** input conversions for reading string and character values: '%s', '%[', and '%c'.

You have two options for how to receive the input from these conversions:

• Provide a buffer to store it in. This is the default. You should provide an argument of type char *.

Warning: To make a robust program, you must make sure that the input (plus its terminating null) cannot possibly exceed the size of the buffer you provide. In general, the only way to do this is to specify a maximum field width one less than the buffer size. If you provide the buffer, always specify a maximum field width to prevent overflow.

• Ask scanf to allocate a big enough buffer, by specifying the 'a' flag character. This is a GNU extension. You should provide an argument of type char ** for the buffer address to be stored in. See Section 11.11.6 [Dynamic String Input], page 180.

The '%c' conversion is the simplest: it matches a fixed number of characters, always. The maximum field with says how many characters to read; if you don't specify the maximum, the default is 1. This conversion doesn't append a null character to the end of the text it reads. It also does not skip over initial whitespace characters. It reads precisely the next n characters, and fails if it cannot get that many. Since there is always a maximum field width with '%c' (whether specified, or 1 by default), you can always prevent overflow by making the buffer long enough.

The '%s' conversion matches a string of non-whitespace characters. It skips and discards initial whitespace, but stops when it encounters more whitespace after having read something. It stores a null character at the end of the text that it reads.

For example, reading the input:

hello, world

with the conversion '%10c' produces "hello, wo", but reading the same input with the conversion '%10s' produces "hello,".

Warning: If you do not specify a field width for '%s', then the number of characters read is limited only by where the next whitespace character appears. This almost certainly means that invalid input can make your program crash—which is a bug.

To read in characters that belong to an arbitrary set of your choice, use the '%[' conversion. You specify the set between the '[' character and a following ']' character, using the same syntax used in regular expressions. As special cases:

- A literal ']' character can be specified as the first character of the set.
- An embedded '-' character (that is, one that is not the first or last character of the set) is used to specify a range of characters.
- If a caret character '^' immediately follows the initial '[', then the set of allowed input characters is the everything except the characters listed.

The '%[' conversion does not skip over initial whitespace characters.

Here are some examples of '%[' conversions and what they mean:

'%25[1234567890]'

Matches a string of up to 25 digits.

'%25 [] []' Matches a string of up to 25 square brackets.

'%25[^\f\n\r\t\v]'

Matches a string up to 25 characters long that doesn't contain any of the standard whitespace characters. This is slightly different from '%s', because if the input begins

with a whitespace character, '%[' reports a matching failure while '%s' simply discards the initial whitespace.

 $\frac{25[a-z]}{}$

Matches up to 25 lowercase characters.

One more reminder: the '%s' and '%[' conversions are **dangerous** if you don't specify a maximum width or use the 'a' flag, because input too long would overflow whatever buffer you have provided for it. No matter how long your buffer is, a user could supply input that is longer. A well-written program reports invalid input with a comprehensible error message, not with a crash.

11.11.6 Dynamically Allocating String Conversions

A GNU extension to formatted input lets you safely read a string with no maximum size. Using this feature, you don't supply a buffer; instead, scanf allocates a buffer big enough to hold the data and gives you its address. To use this feature, write 'a' as a flag character, as in '%as' or '%a[0-9a-z]'.

The pointer argument you supply for where to store the input should have type char **. The scanf function allocates a buffer and stores its address in the word that the argument points to. You should free the buffer with free when you no longer need it.

Here is an example of using the 'a' flag with the '%[...]' conversion specification to read a "variable assignment" of the form 'variable = value'.

11.11.7 Other Input Conversions

This section describes the miscellaneous input conversions.

The '%p' conversion is used to read a pointer value. It recognizes the same syntax as is used by the '%p' output conversion for printf. The corresponding argument should be of type void **; that is, the address of a place to store a pointer.

The resulting pointer value is not guaranteed to be valid if it was not originally written during the same program execution that reads it in.

The '%n' conversion produces the number of characters read so far by this call. The corresponding argument should be of type int *. This conversion works in the same way as the '%n' conversion for printf; see Section 11.9.6 [Other Output Conversions], page 157, for an example.

The '%n' conversion is the only mechanism for determining the success of literal matches or conversions with suppressed assignments. If the '%n' follows the locus of a matching failure, then no value is stored for it since scanf returns before processing the '%n'. If you store -1 in that argument slot before calling scanf, the presence of -1 after scanf indicates an error occurred before the '%n' was reached.

Finally, the '%%' conversion matches a literal '%' character in the input stream, without using an argument. This conversion does not permit any flags, field width, or type modifier to be specified.

11.11.8 Formatted Input Functions

Here are the descriptions of the functions for performing formatted input. Prototypes for these functions are in the header file 'stdio.h'.

int scanf (const char *template, ...)

Function

The scanf function reads formatted input from the stream stdin under the control of the template string template. The optional arguments are pointers to the places which receive the resulting values.

The return value is normally the number of successful assignments. If an end-of-file condition is detected before any matches are performed (including matches against whitespace and literal characters in the template), then EOF is returned.

The GNU C Library

int fscanf (FILE *stream, const char *template, ...)

182

Function

This function is just like scanf, except that the input is read from the stream stream instead of stdin.

int sscanf (const char *s, const char *template, ...)

Function

This is like **scanf**, except that the characters are taken from the null-terminated string s instead of from a stream. Reaching the end of the string is treated as an end-of-file condition.

The behavior of this function is undefined if copying takes place between objects that overlap—for example, if s is also given as an argument to receive a string read under control of the '%s' conversion.

11.11.9 Variable Arguments Input Functions

The functions vscanf and friends are provided so that you can define your own variadic scanf-like functions that make use of the same internals as the built-in formatted output functions. These functions are analogous to the vprintf series of output functions. See Section 11.9.9 [Variable Arguments Output], page 162, for important information on how to use them.

Portability Note: The functions listed in this section are GNU extensions.

int vscanf (const char *template, va_list ap)

Function

This function is similar to **scanf** except that, instead of taking a variable number of arguments directly, it takes an argument list pointer ap of type **va_list** (see Section A.2 [Variadic Functions], page 564).

int vfscanf (FILE *stream, const char *template, va_list ap)

Function

This is the equivalent of fscanf with the variable argument list specified directly as for vscanf.

int vsscanf (const char *s, const char *template, va_list ap)

Function

This is the equivalent of **sscanf** with the variable argument list specified directly as for **vscanf**.

11.12 Block Input/Output

This section describes how to do input and output operations on blocks of data. You can use these functions to read and write binary data, as well as to read and write text in fixed-size blocks instead of by characters or lines.

Binary files are typically used to read and write blocks of data in the same format as is used to represent the data in a running program. In other words, arbitrary blocks of memory—not just character or string objects—can be written to a binary file, and meaningfully read in again by the same program.

Storing data in binary form is often considerably more efficient than using the formatted I/O functions. Also, for floating-point numbers, the binary form avoids possible loss of precision in the conversion process. On the other hand, binary files can't be examined or modified easily using many standard file utilities (such as text editors), and are not portable between different implementations of the language, or different kinds of computers.

These functions are declared in 'stdio.h'.

size_t fread (void *data, size_t size, size_t count, FILE *stream) Function

This function reads up to *count* objects of size *size* into the array *data*, from the stream *stream*. It returns the number of objects actually read, which might be less than *count* if a read error occurs or the end of the file is reached. This function returns a value of zero (and doesn't read anything) if either *size* or *count* is zero.

If fread encounters end of file in the middle of an object, it returns the number of complete objects read, and discards the partial object. Therefore, the stream remains at the actual end of the file.

This function writes up to *count* objects of size *size* from the array *data*, to the stream *stream*. The return value is normally *count*, if the call succeeds. Any other value indicates some sort of error, such as running out of space.

The GNU C Library

11.13 End-Of-File and Errors

Many of the functions described in this chapter return the value of the macro EOF to indicate unsuccessful completion of the operation. Since EOF is used to report both end of file and random errors, it's often better to use the feof function to check explicitly for end of file and ferror to check for errors. These functions check indicators that are part of the internal state of the stream object, indicators set if the appropriate condition was detected by a previous I/O operation on that stream.

These symbols are declared in the header file 'stdio.h'.

int EOF Macro

This macro is an integer value that is returned by a number of functions to indicate an end-of-file condition, or some other error situation. With the GNU library, EOF is -1. In other libraries, its value may be some other negative number.

void clearerr (FILE *stream)

Function

This function clears the end-of-file and error indicators for the stream stream.

The file positioning functions (see Section 11.15 [File Positioning], page 186) also clear the end-of-file indicator for the stream.

int feof (FILE *stream)

Function

The feof function returns nonzero if and only if the end-of-file indicator for the stream stream is set.

int ferror (FILE *stream)

Function

The ferror function returns nonzero if and only if the error indicator for the stream stream is set, indicating that an error has occurred on a previous operation on the stream.

In addition to setting the error indicator associated with the stream, the functions that operate on streams also set error in the same way as the corresponding low-level functions that operate on file descriptors. For example, all of the functions that perform output to a stream—such as fputc, printf, and fflush—are implemented in terms of write, and all of the error conditions defined for write are meaningful for these functions. For more information about the descriptor-level I/O functions, see Chapter 12 [Low-Level I/O], page 203.

11.14 Text and Binary Streams

The GNU system and other POSIX-compatible operating systems organize all files as uniform sequences of characters. However, some other systems make a distinction between files containing text and files containing binary data, and the input and output facilities of ANSI C provide for this distinction. This section tells you how to write programs portable to such systems.

When you open a stream, you can specify either a text stream or a binary stream. You indicate that you want a binary stream by specifying the 'b' modifier in the opentype argument to fopen; see Section 11.3 [Opening Streams], page 140. Without this option, fopen opens the file as a text stream.

Text and binary streams differ in several ways:

- The data read from a text stream is divided into *lines* which are terminated by newline ('\n') characters, while a binary stream is simply a long series of characters. A text stream might on some systems fail to handle lines more than 254 characters long (including the terminating newline character).
- On some systems, text files can contain only printing characters, horizontal tab characters, and newlines, and so text streams may not support other characters. However, binary streams can handle any character value.
- Space characters that are written immediately preceding a newline character in a text stream may disappear when the file is read in again.
- More generally, there need not be a one-to-one mapping between characters that are read from or written to a text stream, and the characters in the actual file.

Since a binary stream is always more capable and more predictable than a text stream, you might wonder what purpose text streams serve. Why not simply always use binary streams? The answer is that on these operating systems, text and binary streams use different file formats, and the only way to read or write "an ordinary file of text" that can work with other text-oriented programs is through a text stream.

In the GNU library, and on all POSIX systems, there is no difference between text streams and binary streams. When you open a stream, you get the same kind of stream regardless of whether you ask for binary. This stream can handle any file content, and has none of the restrictions that text streams sometimes have.

11.15 File Positioning

The file position of a stream describes where in the file the stream is currently reading or writing. I/O on the stream advances the file position through the file. In the GNU system, the file position is represented as an integer, which counts the number of bytes from the beginning of the file. See Section 10.1.2 [File Position], page 133.

During I/O to an ordinary disk file, you can change the file position whenever you wish, so as to read or write any portion of the file. Some other kinds of files may also permit this. Files which support changing the file position are sometimes referred to as *random-access* files.

You can use the functions in this section to examine or modify the file position indicator associated with a stream. The symbols listed below are declared in the header file 'stdio.h'.

long int ftell (FILE *stream)

Function

This function returns the current file position of the stream stream.

This function can fail if the stream doesn't support file positioning, or if the file position can't be represented in a long int, and possibly for other reasons as well. If a failure occurs, a value of -1 is returned.

int fseek (FILE *stream, long int offset, int whence)

Function

The fseek function is used to change the file position of the stream stream. The value of whence must be one of the constants SEEK_SET, SEEK_CUR, or SEEK_END, to indicate whether the offset is relative to the beginning of the file, the current file position, or the end of the file, respectively.

This function returns a value of zero if the operation was successful, and a nonzero value to indicate failure. A successful call also clears the end-of-file indicator of *stream* and discards any characters that were "pushed back" by the use of ungetc.

fseek either flushes any buffered output before setting the file position or else remembers it so it will be written later in its proper place in the file.

Portability Note: In non-POSIX systems, ftell and fseek might work reliably only on binary streams. See Section 11.14 [Binary Streams], page 185.

The following symbolic constants are defined for use as the *whence* argument to fseek. They are also used with the lseek function (see Section 12.2 [I/O Primitives], page 206) and to specify offsets for file locks (see Section 12.7 [Control Operations], page 219).

int SEEK_SET Macro

This is an integer constant which, when used as the whence argument to the fseek function, specifies that the offset provided is relative to the beginning of the file.

int SEEK_CUR Macro

This is an integer constant which, when used as the whence argument to the fseek function, specifies that the offset provided is relative to the current file position.

int SEEK_END Macro

This is an integer constant which, when used as the whence argument to the fseek function, specifies that the offset provided is relative to the end of the file.

void rewind (FILE *stream)

Function

The rewind function positions the stream stream at the begining of the file. It is equivalent to calling fseek on the stream with an offset argument of OL and a whence argument of SEEK_SET, except that the return value is discarded and the error indicator for the stream is reset.

These three aliases for the 'SEEK_...' constants exist for the sake of compatibility with older BSD systems. They are defined in two different header files: 'fcntl.h' and 'sys/file.h'.

L_SET An alias for SEEK_SET.

L_INCR An alias for SEEK_CUR.

L_XTND An alias for SEEK_END.

11.16 Portable File-Position Functions

On the GNU system, the file position is truly a character count. You can specify any character count value as an argument to fseek and get reliable results for any random access file. However, some ANSI C systems do not represent file positions in this way.

On some systems where text streams truly differ from binary streams, it is impossible to represent the file position of a text stream as a count of characters from the beginning of the file. For example, the file position on some systems must encode both a record offset within the file, and a character offset within the record.

As a consequence, if you want your programs to be portable to these systems, you must observe certain rules:

- The value returned from ftell on a text stream has no predictable relationship to the number of characters you have read so far. The only thing you can rely on is that you can use it subsequently as the offset argument to fseek to move back to the same file position.
- In a call to fseek on a text stream, either the offset must either be zero; or whence must be SEEK_SET and the offset must be the result of an earlier call to ftell on the same stream.
- The value of the file position indicator of a text stream is undefined while there are characters that have been pushed back with ungetc that haven't been read or discarded. See Section 11.8 [Unreading], page 148.

But even if you observe these rules, you may still have trouble for long files, because ftell and fseek use a long int value to represent the file position. This type may not have room to encode all the file positions in a large file.

So if you do want to support systems with peculiar encodings for the file positions, it is better to use the functions fgetpos and fsetpos instead. These functions represent the file position using the data type fpos_t, whose internal representation varies from system to system.

These symbols are declared in the header file 'stdio.h'.

 $fpos_t$ Data Type

This is the type of an object that can encode information about the file position of a stream, for use by the functions fgetpos and fsetpos.

In the GNU system, fpos_t is equivalent to off_t or long int. In other systems, it might have a different internal representation.

int fgetpos (FILE *stream, fpos_t *position)

Function

This function stores the value of the file position indicator for the stream stream in the fpos_t object pointed to by position. If successful, fgetpos returns zero; otherwise it returns a nonzero value and stores an implementation-defined positive value in errno.

int fsetpos (FILE *stream, const fpos_t position)

Function

This function sets the file position indicator for the stream stream to the position position, which must have been set by a previous call to fgetpos on the same stream. If successful, fsetpos clears the end-of-file indicator on the stream, discards any characters that were "pushed back" by the use of ungetc, and returns a value of zero. Otherwise, fsetpos returns a nonzero value and stores an implementation-defined positive value in errno.

11.17 Stream Buffering

Characters that are written to a stream are normally accumulated and transmitted asynchronously to the file in a block, instead of appearing as soon as they are output by the application program. Similarly, streams often retrieve input from the host environment in blocks rather than on a character-by-character basis. This is called *buffering*.

If you are writing programs that do interactive input and output using streams, you need to understand how buffering works when you design the user interface to your program. Otherwise, you might find that output (such as progress or prompt messages) doesn't appear when you intended it to, or that input typed by the user is made available by lines instead of by single characters, or other unexpected behavior.

This section deals only with controlling when characters are transmitted between the stream and the file or device, and *not* with how things like echoing, flow control, and the like are handled on specific classes of devices. For information on common control operations on terminal devices, see Chapter 16 [Low-Level Terminal Interface], page 321.

You can bypass the stream buffering facilities altogether by using the low-level input and output functions that operate on file descriptors instead. See Chapter 12 [Low-Level I/O], page 203.

11.17.1 Buffering Concepts

There are three different kinds of buffering strategies:

- Characters written to or read from an *unbuffered* stream are transmitted individually to or from the file as soon as possible.
- Characters written to or read from a *line buffered* stream are transmitted to or from the file in blocks when a newline character is encountered.
- Characters written to or read from a fully buffered stream are transmitted to or from the file in blocks of arbitrary size.

Newly opened streams are normally fully buffered, with one exception: a stream connected to an interactive device such as a terminal is initially line buffered. See Section 11.17.3 [Controlling Buffering], page 191, for information on how to select a different kind of buffering.

The use of line buffering for interactive devices implies that output messages ending in a newline will appear immediately—which is usually what you want. Output that doesn't end in a newline might or might not show up immediately, so if you want them to appear immediately, you should flush buffered output explicitly with fflush, as described in Section 11.17.2 [Flushing Buffers], page 190.

Line buffering is a good default for terminal input as well, because most interactive programs read commands that are normally single lines. The program should be able to execute each line right away. A line buffered stream permits this, whereas a fully buffered stream would always read enough text to fill the buffer before allowing the program to read any of it. Line buffering also fits in with the usual input-editing facilities of most operating systems, which work within a line of input.

Some programs need an unbuffered terminal input stream. These include programs that read single-character commands (like Emacs) and programs that do their own input editing (such as those that use readline). In order to read a character at a time, it is not enough to turn off buffering in the input stream; you must also turn off input editing in the operating system. This requires changing the terminal mode (see Section 16.4 [Terminal Modes], page 323). If you want to change the terminal modes, you have to do this separately—merely using an unbuffered stream does not change the modes.

11.17.2 Flushing Buffers

Flushing output on a buffered stream means transmitting all accumulated characters to the file. There are many circumstances when buffered output on a stream is flushed automatically:

- When you try to do output and the output buffer is full.
- When the stream is closed. See Section 11.4 [Closing Streams], page 142.
- When the program terminates by calling exit. See Section 22.3.1 [Normal Termination], page 476.
- When a newline is written, if the stream is line buffered.
- Whenever an input operation on any stream actually reads data from its file.

If you want to flush the buffered output at another time, call fflush, which is declared in the header file 'stdio.h'.

int fflush (FILE *stream)

Function

This function causes any buffered output on *stream* to be delivered to the file. If *stream* is a null pointer, then **fflush** causes buffered output on *all* open output streams to be flushed.

This function returns EOF if a write error occurs, or zero otherwise.

Compatibility Note: Some brain-damaged operating systems have been known to be so thoroughly fixated on line-oriented input and output that flushing a line buffered stream causes a newline to be written! Fortunately, this "feature" seems to be becoming less common. You do not need to worry about this in the GNU system.

11.17.3 Controlling Which Kind of Buffering

After opening a stream (but before any other operations have been performed on it), you can explicitly specify what kind of buffering you want it to have using the **setvbuf** function.

The facilities listed in this section are declared in the header file 'stdio.h'.

int setvbuf (FILE *stream, char *buf, int mode, size_t size)

Function

This function is used to specify that the stream stream should have the buffering mode mode, which can be either _IOFBF (for full buffering), _IOLBF (for line buffering), or _IONBF (for unbuffered input/output).

If you specify a null pointer as the *buf* argument, then **setvbuf** allocates a buffer itself using malloc. This buffer will be freed when you close the stream.

Otherwise, buf should be a character array that can hold at least size characters. You should not free the space for this array as long as the stream remains open and this array remains its buffer. You should usually either allocate it statically, or malloc (see Section 3.3 [Unconstrained Allocation], page 30) the buffer. Using an automatic array is not a good idea unless you close the file before exiting the block that declares the array.

While the array remains a stream buffer, the stream I/O functions will use the buffer for their internal purposes. You shouldn't try to access the values in the array directly while the stream is using it for buffering.

The **setvbuf** function returns zero on success, or a nonzero value if the value of *mode* is not valid or if the request could not be honored.

int JOFBF Macro

The value of this macro is an integer constant expression that can be used as the *mode* argument to the **setvbuf** function to specify that the stream should be fully buffered.

int LIOLBF Macro

The value of this macro is an integer constant expression that can be used as the *mode* argument to the **setvbuf** function to specify that the stream should be line buffered.

int IONBF Macro

The value of this macro is an integer constant expression that can be used as the *mode* argument to the **setvbuf** function to specify that the stream should be unbuffered.

int BUFSIZ Macro

The value of this macro is an integer constant expression that is good to use for the size argument to setvbuf. This value is guaranteed to be at least 256.

The value of BUFSIZ is chosen on each system so as to make stream I/O efficient. So it is a good idea to use BUFSIZ as the size for the buffer when you call setvbuf.

Actually, you can get an even better value to use for the buffer size by means of the fstat system call: it is found in the st_blksize field of the file attributes. See Section 13.8.1 [Attribute Meanings], page 246.

Sometimes people also use BUFSIZ as the allocation size of buffers used for related purposes, such as strings used to receive a line of input with fgets (see Section 11.6 [Character Input], page 144). There is no particular reason to use BUFSIZ for this instead of any other integer, except that it might lead to doing I/O in chunks of an efficient size.

void setbuf (FILE *stream, char *buf)

Function

If buf is a null pointer, the effect of this function is equivalent to calling setvbuf with a mode argument of _IONBF. Otherwise, it is equivalent to calling setvbuf with buf, and a mode of _IOFBF and a size argument of BUFSIZ.

The setbuf function is provided for compatibility with old code; use setvbuf in all new programs.

void setbuffer (FILE *stream, char *buf, size_t size)

Function

If buf is a null pointer, this function makes stream unbuffered. Otherwise, it makes stream fully buffered using buf as the buffer. The size argument specifies the length of buf.

This function is provided for compatibility with old BSD code. Use setvbuf instead.

void setlinebuf (FILE *stream)

Function

This function makes stream be line buffered, and allocates the buffer for you.

This function is provided for compatibility with old BSD code. Use setvbuf instead.

11.18 Temporary Files

If you need to use a temporary file in your program, you can use the tmpfile function to open it. Or you can use the tmpnam function make a name for a temporary file and then open it in the usual way with fopen.

These facilities are declared in the header file 'stdio.h'.

FILE * tmpfile (void)

Function

This function creates a temporary binary file for update mode, as if by calling fopen with mode "wb+". The file is deleted automatically when it is closed or when the program terminates. (On some other ANSI C systems the file may fail to be deleted if the program terminates abnormally).

char * tmpnam (char *result)

Function

This function constructs and returns a file name that is a valid file name and that does not name any existing file. If the *result* argument is a null pointer, the return value is a pointer to an internal static string, which might be modified by subsequent calls. Otherwise, the *result* argument should be a pointer to an array of at least L_tmpnam characters, and the result is written into that array.

It is possible for tmpnam to fail if you call it too many times. This is because the fixed length of a temporary file name gives room for only a finite number of different names. If tmpnam fails, it returns a null pointer.

int L_tmpnam Macro

The value of this macro is an integer constant expression that represents the minimum allocation size of a string large enough to hold the file name generated by the tmpnam function.

int TMP_MAX Macro

The macro TMP_MAX is a lower bound for how many temporary names you can create with tmpnam. You can rely on being able to call tmpnam at least this many times before it might fail saying you have made too many temporary file names.

With the GNU library, you can create a very large number of temporary file names—if you actually create the files, you will probably run out of disk space before you run out of names. Some other systems have a fixed, small limit on the number of temporary files. The limit is never less than 25.

char * tempnam (const char *dir, const char *prefix)

Function

This function generates a unique temporary filename. If *prefix* is not a null pointer, up to five characters of this string are used as a prefix for the file name.

The directory prefix for the temporary file name is determined by testing each of the following, in sequence. The directory must exist and be writable.

- The environment variable TMPDIR, if it is defined.
- The dir argument, if it is not a null pointer.
- The value of the P_tmpdir macro.
- The directory '/tmp'.

This function is defined for SVID compatibility.

char * P_tmpdir

SVID Macro

This macro is the name of the default directory for temporary files.

11.19 Other Kinds of Streams

The GNU library provides ways for you to define additional kinds of streams that do not necessarily correspond to an open file.

One such type of stream takes input from or writes output to a string. These kinds of streams are used internally to implement the **sprintf** and **sscanf** functions. You can also create such a stream explicitly, using the functions described in Section 11.19.1 [String Streams], page 195.

More generally, you can define streams that do input/output to arbitrary objects using functions supplied by your program. This protocol is discussed in Section 11.19.3 [Custom Streams], page 199.

Portability Note: The facilities described in this section are specific to GNU. Other systems or C implementations might or might not provide equivalent functionality.

11.19.1 String Streams

The fmemopen and open_memstream functions allow you to do I/O to a string or memory buffer. These facilities are declared in 'stdio.h'.

FILE * fmemopen (void *buf, size_t size, const char *opentype)

Function

This function opens a stream that allows the access specified by the opentype argument,
that reads from or writes to the buffer specified by the argument buf. This array must

be at least size bytes long.

If you specify a null pointer as the *buf* argument, fmemopen dynamically allocates (as with malloc; see Section 3.3 [Unconstrained Allocation], page 30) an array *size* bytes long. This is really only useful if you are going to write things to the buffer and then read them back in again, because you have no way of actually getting a pointer to the buffer (for this, try open_memstream, below). The buffer is freed when the stream is open.

The argument opentype is the same as in fopen (See Section 11.3 [Opening Streams], page 140). If the opentype specifies append mode, then the initial file position is set to the first null character in the buffer. Otherwise the initial file position is at the beginning of the buffer.

When a stream open for writing is flushed or closed, a null character (zero byte) is written at the end of the buffer if it fits. You should add an extra byte to the *size* argument to account for this. Attempts to write more than *size* bytes to the buffer result in an error.

For a stream open for reading, null characters (zero bytes) in the buffer do not count as "end of file". Read operations indicate end of file only when the file position advances past size bytes. So, if you want to read characters from a null-terminated string, you should supply the length of the string as the size argument.

Here is an example of using fmemopen to create a stream for reading from a string:

```
#include <stdio.h>
static char buffer[] = "foobar";
int
main (void)
{
   int ch;
   FILE *stream;

   stream = fmemopen (buffer, strlen (buffer), "r");
   while ((ch = fgetc (stream)) != EOF)
        printf ("Got %c\n", ch);
   fclose (stream);

   return 0;
}
```

This program produces the following output:

```
Got f
Got o
Got o
Got b
Got a
Got r
```

FILE * open_memstream (char **ptr, size_t *sizeloc)

Function

This function opens a stream for writing to a buffer. The buffer is allocated dynamically (as with malloc; see Section 3.3 [Unconstrained Allocation], page 30) and grown as necessary.

When the stream is closed with fclose or flushed with fflush, the locations ptr and sizeloc are updated to contain the pointer to the buffer and its size. The values thus stored remain valid only as long as no further output on the stream takes place. If you do more output, you must flush the stream again to store new values before you use them again.

A null character is written at the end of the buffer. This null character is not included in the size value stored at sizeloc.

You can move the stream's file position with fseek (see Section 11.15 [File Positioning], page 186). Moving the file position past the end of the data already written fills the intervening space with zeroes.

Here is an example of using open_memstream:

```
#include <stdio.h>
int
main (void)
{
   char *bp;
   size_t size;
   FILE *stream;
```

```
stream = open_memstream (&bp, &size);
fprintf (stream, "hello");
fflush (stream);
printf ("buf = %s, size = %d\n", bp, size);
fprintf (stream, ", world");
fclose (stream);
printf ("buf = %s, size = %d\n", bp, size);
return 0;
}
```

This program produces the following output:

```
buf = 'hello', size = 5
buf = 'hello, world', size = 12
```

11.19.2 Obstack Streams

You can open an output stream that puts it data in an obstack. See Section 3.4 [Obstacks], page 40.

FILE * open_obstack_stream (struct obstack *obstack)

Function

This function opens a stream for writing data into the obstack obstack. This starts an object in the obstack and makes it grow as data is written (see Section 3.4.6 [Growing Objects], page 46).

Calling fflush on this stream updates the current size of the object to match the amount of data that has been written. After a call to fflush, you can examine the object temporarily.

You can move the file position of an obstack stream with fseek (see Section 11.15 [File Positioning], page 186). Moving the file position past the end of the data written fills the intervening space with zeros.

To make the object permanent, update the obstack with fflush, and then use obstack_finish to finalize the object and get its address. The following write to the stream starts a new object in the obstack, and later writes add to that object until you do another fflush and obstack_finish.

But how do you find out how long the object is? You can get the length in bytes by calling obstack_object_size (see Section 3.4.8 [Status of an Obstack], page 49), or you can null-terminate the object like this:

```
obstack_1grow (obstack, 0);
```

Whichever one you do, you must do it before calling obstack_finish. (You can do both if you wish.)

Here is a sample function that uses open_obstack_stream:

```
char *
make_message_string (const char *a, int b)
{
   FILE *stream = open_obstack_stream (&message_obstack);
   output_task (stream);
   fprintf (stream, ": ");
   fprintf (stream, a, b);
   fprintf (stream, "\n");
   fclose (stream);
   obstack_1grow (&message_obstack, 0);
   return obstack_finish (&message_obstack);
}
```

11.19.3 Programming Your Own Custom Streams

This section describes how you can make a stream that gets input from an arbitrary data source or writes output to an arbitrary data sink programmed by you. We call these *custom streams*.

11.19.3.1 Custom Streams and Cookies

Inside every custom stream is a special object called the *cookie*. This is an object supplied by you which records where to fetch or store the data read or written. It is up to you to define a data type to use for the cookie. The stream functions in the library never refer directly to its contents, and they don't even know what the type is; they record its address with type void *.

To implement a custom stream, you must specify how to fetch or store the data in the specified place. You do this by defining hook functions to read, write, change "file position", and close the

200 The GNU C Library

stream. All four of these functions will be passed the stream's cookie so they can tell where to fetch or store the data. The library functions don't know what's inside the cookie, but your functions will know.

When you create a custom stream, you must specify the cookie pointer, and also the four hook functions stored in a structure of type struct cookie_io_functions.

These facilities are declared in 'stdio.h'.

struct cookie_io_functions

Data Type

This is a structure type that holds the functions that define the communications protocol between the stream and its cookie. It has the following members:

cookie_read_function *read

This is the function that reads data from the cookie. If the value is a null pointer instead of a function, then read operations on the stream always return EOF.

cookie_write_function *write

This is the function that writes data to the cookie. If the value is a null pointer instead of a function, then data written to the stream is discarded.

cookie_seek_function *seek

This is the function that performs the equivalent of file positioning on the cookie. If the value is a null pointer instead of a function, calls to fseek on this stream return an ESPIPE error.

cookie close function *close

This function performs any appropriate cleanup on the cookie when closing the stream. If the value is a null pointer instead of a function, nothing special is done to close the cookie when the stream is closed.

FILE * fopencookie (void *cookie, const char *opentype, struct cookie_functions io functions)

This function actually creates the stream for communicating with the *cookie* using the functions in the *io_functions* argument. The *opentype* argument is interpreted as for fopen; see Section 11.3 [Opening Streams], page 140. (But note that the "truncate on open" option is ignored.) The new stream is fully buffered.

The fopencookie function returns the newly created stream, or a null pointer in case of an error.

11.19.3.2 Custom Stream Hook Functions

Here are more details on how you should define the four hook functions that a custom stream needs.

You should define the function to read data from the cookie as:

```
ssize_t reader (void *cookie, void *buffer, size_t size)
```

This is very similar to the **read** function; see Section 12.2 [I/O Primitives], page 206. Your function should transfer up to *size* bytes into the *buffer*, and return the number of bytes read, or zero to indicate end-of-file. You can return a value of -1 to indicate an error.

You should define the function to write data to the cookie as:

```
ssize_t writer (void *cookie, const void *buffer, size_t size)
```

This is very similar to the write function; see Section 12.2 [I/O Primitives], page 206. Your function should transfer up to *size* bytes from the buffer, and return the number of bytes written. You can return a value of -1 to indicate an error.

You should define the function to perform seek operations on the cookie as:

```
int seeker (void *cookie, fpos_t *position, int whence)
```

For this function, the *position* and *whence* arguments are interpreted as for fgetpos; see Section 11.16 [Portable Positioning], page 187. In the GNU library, fpos_t is equivalent to off_t or long int, and simply represents the number of bytes from the beginning of the file.

202 The GNU C Library

After doing the seek operation, your function should store the resulting file position relative to the beginning of the file in position. Your function should return a value of 0 on success and -1 to indicate an error.

You should define the function to do cleanup operations on the cookie appropriate for closing the stream as:

int cleaner (void *cookie)

Your function should return -1 to indicate an error, and 0 otherwise.

cookie_read_function

Data Type

This is the data type that the read function for a custom stream should have. If you declare the function as shown above, this is the type it will have.

cookie_write_function

Data Type

The data type of the write function for a custom stream.

cookie_seek_function

Data Type

The data type of the seek function for a custom stream.

cookie_close_function

Data Type

The data type of the close function for a custom stream.

12 Low-Level Input/Output

This chapter describes functions for performing low-level input/output operations on file descriptors. These functions include the primitives for the higher-level I/O functions described in Chapter 11 [I/O on Streams], page 139, as well as functions for performing low-level control operations for which there are no equivalents on streams.

Stream-level I/O is more flexible and usually more convenient; therefore, programmers generally use the descriptor-level functions only when necessary. These are some of the usual reasons:

- For reading binary files in large chunks.
- For reading an entire file into core before parsing it.
- To perform operations other than data transfer, which can only be done with a descriptor. (You can use fileno to get the descriptor corresponding to a stream.)
- To pass descriptors to a child process. (The child can create its own stream to use a descriptor that it inherits, but cannot inherit a stream directly.)

12.1 Opening and Closing Files

This section describes the primitives for opening and closing files using file descriptors. The open and creat functions are declared in the header file 'fcntl.h', while close is declared in 'unistd.h'.

int open (const char *filename, int flags[, mode_t mode])

Function

The open function creates and returns a new file descriptor for the file named by *filename*. Initially, the file position indicator for the file is at the beginning of the file. The argument *mode* is used only when a file is created, but it doesn't hurt to supply the argument in any case.

The flags argument controls how the file is to be opened. This is a bit mask; you create the value by the bitwise OR of the appropriate parameters (using the '|' operator in C).

The flags argument must include exactly one of these values to specify the file access mode:

O_RDONLY Open the file for read access.

O_WRONLY Open the file for write access.

O_RDWR Open the file for both reading and writing.

The flags argument can also include any combination of these flags:

O_APPEND If set, then all write operations write the data at the end of the file, extending it, regardless of the current file position.

O_CREAT If set, the file will be created if it doesn't already exist.

O_EXCL If both O_CREAT and O_EXCL are set, then open fails if the specified file already exists.

O_NOCTTY If filename names a terminal device, don't make it the controlling terminal for the process. See Chapter 24 [Job Control], page 495, for information about what it means to be the controlling terminal.

O_NONBLOCK

This sets nonblocking mode. This option is usually only useful for special files such as FIFOs (see Chapter 14 [Pipes and FIFOs], page 263) and devices such as terminals. Normally, for these files, open blocks until the file is "ready". If O_NONBLOCK is set, open returns immediately.

The O_NONBLOCK bit also affects read and write: It permits them to return immediately with a failure status if there is no input immediately available (read), or if the output can't be written immediately (write).

O_TRUNC If the file exists and is opened for write access, truncate it to zero length.

This option is only useful for regular files, not special files such as directories or FIFOs.

For more information about these symbolic constants, see Section 12.10 [File Status Flags], page 224.

The normal return value from open is a non-negative integer file descriptor. In the case of an error, a value of -1 is returned instead. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following error conditions are defined for this function:

EACCES The file exists but is not readable/writable as requested by the flags argument.

EEXIST	Both O_CREAT and O_EXCL are set, and the named file already exists.
EINTR	The open operation was interrupted by a signal. See Section 21.5 [Interrupted Primitives], page 438.
EISDIR	The flags argument specified write access, and the file is a directory.
EMFILE	The process has too many files open.
ENFILE	The entire system, or perhaps the file system which contains the directory, cannot support any additional open files at the moment. (This problem cannot happen on the GNU system.)
ENOENT	The named file does not exist, but O_CREAT is not specified.
ENOSPC	The directory or file system that would contain the new file cannot be extended, because there is no disk space left.
ENXIO	O_NONBLOCK and O_WRONLY are both set in the flags argument, the file named by filename is a FIFO (see Chapter 14 [Pipes and FIFOs], page 263), and no process has the file open for reading.
EROFS	The file resides on a read-only file system and any of O_WRONLY , O_RDWR , O_CREAT , and O_TRUNC are set in the flags argument.

The open function is the underlying primitive for the fopen and freopen functions, that create streams.

```
int creat (const char *filename, mode_t mode)
    This function is obsolete. The call
```

Obsolete function

creat (filename, mode)

is equivalent to

```
open (filename, O_WRONLY | O_CREAT | O_TRUNC, mode)
```

int close (int filedes)

Function

The function close closes the file descriptor filedes. Closing a file has the following consequences:

• The file descriptor is deallocated.

- Any record locks owned by the process on the file are unlocked.
- When all file descriptors associated with a pipe or FIFO have been closed, any unread data is discarded.

The normal return value from close is 0; a value of -1 is returned in case of failure. The following error conditions are defined for this function:

EBADF The filedes argument is not a valid file descriptor.

EINTR The call was interrupted by a signal. See Section 21.5 [Interrupted Primitives], page 438. Here's an example of how to handle EINTR properly:

TEMP_FAILURE_RETRY (close (desc));

To close a stream, call fclose (see Section 11.4 [Closing Streams], page 142) instead of trying to close its underlying file descriptor with close. This flushes any buffered output and updates the stream object to indicate that it is closed.

12.2 Input and Output Primitives

This section describes the functions for performing primitive input and output operations on file descriptors: read, write, and lseek. These functions are declared in the header file 'unistd.h'.

ssize_t Data Type

This data type is used to represent the sizes of blocks that can be read or written in a single operation. It is similar to size_t, but must be a signed type.

ssize_t read (int filedes, void *buffer, size_t size)

Function

The read function reads up to size bytes from the file with descriptor filedes, storing the results in the buffer. (This is not necessarily a character string and there is no terminating null character added.)

The return value is the number of bytes actually read. This might be less than size; for example, if there aren't that many bytes left in the file or if there aren't that many bytes immediately available. The exact behavior depends on what kind of file it is. Note that reading less than size bytes is not an error.

A value of zero indicates end-of-file (except if the value of the *size* argument is also zero). This is not considered an error. If you keep calling **read** while at end-of-file, it will keep returning zero and doing nothing else.

If read returns at least one character, there is no way you can tell whether end-of-file was reached. But if you did reach the end, the next read will return zero.

In case of an error, read returns -1. The following errno error conditions are defined for this function:

EAGAIN

Normally, when no input is immediately available, read waits for some input. But if the O_NONBLOCK flag is set for the file (see Section 12.10 [File Status Flags], page 224), read returns immediately without reading any data, and reports this error.

Compatibility Note: Most versions of BSD Unix use a different error code for this: EWOULDBLOCK. In the GNU library, EWOULDBLOCK is an alias for EAGAIN, so it doesn't matter which name you use.

On some systems, reading a large amount of data from a character special file can also fail with EAGAIN if the kernel cannot find enough physical memory to lock down the user's pages. This is limited to devices that transfer with direct memory access into the user's memory, which means it does not include terminals, since they always use separate buffers inside the kernel.

EBADF The filedes argument is not a valid file descriptor.

EINTR read was interrupted by a signal while it was waiting for input. See Section 21.5 [Interrupted Primitives], page 438.

For many devices, and for disk files, this error code indicates a hardware error.

EIO also occurs when a background process tries to read from the controlling terminal, and the normal action of stopping the process by sending it a SIGTTIN signal isn't working. This might happen if signal is being blocked or ignored, or because the process group is orphaned. See Chapter 24 [Job Control], page 495, for more information about job control, and Chapter 21 [Signal Handling], page 403, for information about signals.

The read function is the underlying primitive for all of the functions that read from streams, such as fgetc.

ssize_t write (int filedes, const void *buffer, size_t size)

Function

The write function writes up to size bytes from buffer to the file with descriptor filedes. The data in buffer is not necessarily a character string and a null character output like any other character.

The return value is the number of bytes actually written. This is normally the same as size, but might be less (for example, if the physical media being written to fills up).

In the case of an error, write returns -1. The following errno error conditions are defined for this function:

EAGAIN

Normally, write blocks until the write operation is complete. But if the O_NONBLOCK flag is set for the file (see Section 12.7 [Control Operations], page 219), it returns immediately without writing any data, and reports this error. An example of a situation that might cause the process to block on output is writing to a terminal device that supports flow control, where output has been suspended by receipt of a STOP character.

Compatibility Note: Most versions of BSD Unix use a different error code for this: EWOULDBLOCK. In the GNU library, EWOULDBLOCK is an alias for EAGAIN, so it doesn't matter which name you use.

On some systems, writing a large amount of data from a character special file can also fail with EAGAIN if the kernel cannot find enough physical memory to lock down the user's pages. This is limited to devices that transfer with direct memory access into the user's memory, which means it does not include terminals, since they always use separate buffers inside the kernel.

EBADF The filedes argument is not a valid file descriptor.

EFBIG The size of the file is larger than the implementation can support.

EINTR The write operation was interrupted by a signal while it was blocked waiting for completion. See Section 21.5 [Interrupted Primitives], page 438.

For many devices, and for disk files, this error code indicates a hardware error.

EIO also occurs when a background process tries to write to the controlling terminal, and the normal action of stopping the process by sending it a SIGTTOU signal isn't working. This might happen if the signal is being blocked or ignored. See Chapter 24 [Job Control], page 495, for more information about job control, and Chapter 21 [Signal Handling], page 403, for information about signals.

ENOSPC The device is full.

EPIPE This error is returned when you try to write to a pipe or FIFO that isn't open for reading by any process. When this happens, a SIGPIPE signal is also sent to the process; see Chapter 21 [Signal Handling], page 403.

Unless you have arranged to prevent EINTR failures, you should check errno after each failing call to write, and if the error was EINTR, you should simply repeat the call. See Section 21.5 [Interrupted Primitives], page 438. The easy way to do this is with the macro TEMP_FAILURE_RETRY, as follows:

```
nbytes = TEMP_FAILURE_RETRY (write (desc, buffer, count));
```

The write function is the underlying primitive for all of the functions that write to streams, such as fputc.

12.3 Setting the File Position of a Descriptor

Just as you can set the file position of a stream with fseek, you can set the file position of a descriptor with lseek. This specifies the position in the file for the next read or write operation. See Section 11.15 [File Positioning], page 186, for more information on the file position and what it means.

To read the current file position value from a descriptor, use lseek (desc, 0, SEEK_CUR).

off_t lseek (int filedes, off_t offset, int whence)

The lseek function is used to change the file position of the file with descriptor filedes.

The whence argument specifies how the offset should be interpreted in the same way as for the fseek function, and can be one of the symbolic constants SEEK_SET, SEEK_CUR, or SEEK_END.

- SEEK_SET Specifies that whence is a count of characters from the beginning of the file.
- SEEK_CUR Specifies that whence is a count of characters from the current file position.

 This count may be positive or negative.

SEEK_END Specifies that whence is a count of characters from the end of the file. A negative count specifies a position within the current extent of the file; a positive count specifies a position past the current end. If you set the position past the current end, and actually write data, you will extend the file with zeros up to that position.

The return value from lseek is normally the resulting file position, measured in bytes from the beginning of the file. You can use this feature together with SEEK_CUR to read the current file position.

You can set the file position past the current end of the file. This does not by itself make the file longer; lseek never changes the file. But subsequent output at that position will extend the file's size.

If the file position cannot be changed, or the operation is in some way invalid, lseek returns a value of -1. The following errno error conditions are defined for this function:

EBADF The filedes is not a valid file descriptor.

EINVAL The whence argument value is not valid, or the resulting file offset is not valid.

ESPIPE The filedes corresponds to a pipe or FIFO, which cannot be positioned. (There may be other kinds of files that cannot be positioned either, but the behavior is not specified in those cases.)

The lseek function is the underlying primitive for the fseek, ftell and rewind functions, which operate on streams instead of file descriptors.

You can have multiple descriptors for the same file if you open the file more than once, or if you duplicate a descriptor with dup. Descriptors that come from separate calls to open have independent file positions; using lseek on one descriptor has no effect on the other. For example,

```
{
  int d1, d2;
  char buf[4];
  d1 = open ("foo", O_RDONLY);
  d2 = open ("foo", O_RDONLY);
  lseek (d1, 1024, SEEK_SET);
  read (d2, buf, 4);
}
```

will read the first four characters of the file 'foo'. (The error-checking code necessary for a real program has been omitted here for brevity.)

By contrast, descriptors made by duplication share a common file position with the original descriptor that was duplicated. Anything which alters the file position of one of the duplicates, including reading or writing data, affects all of them alike. Thus, for example,

```
{
  int d1, d2, d3;
  char buf1[4], buf2[4];
  d1 = open ("foo", O_RDONLY);
  d2 = dup (d1);
  d3 = dup (d2);
  lseek (d3, 1024, SEEK_SET);
  read (d1, buf1, 4);
  read (d2, buf2, 4);
}
```

will read four characters starting with the 1024'th character of 'foo', and then four more characters starting with the 1028'th character.

off_t Data Type

This is an arithmetic data type used to represent file sizes. In the GNU system, this is equivalent to fpos_t or long int.

These three aliases for the 'SEEK_...' constants exist for the sake of compatibility with older BSD systems. They are defined in two different header files: 'fcntl.h' and 'sys/file.h'.

```
L_SET An alias for SEEK_SET.

L_INCR An alias for SEEK_CUR.
```

L_XTND An alias for SEEK_END.

12.4 Descriptors and Streams

Given an open file descriptor, you can create a stream for it with the fdopen function. You can get the underlying file descriptor for an existing stream with the fileno function. These functions are declared in the header file 'stdio.h'.

FILE * fdopen (int filedes, const char *opentype)

Function

The fdopen function returns a new stream for the file descriptor filedes.

The opentype argument is interpreted in the same way as for the fopen function (see Section 11.3 [Opening Streams], page 140), except that the 'b' option is not permitted; this is because GNU makes no distinction between text and binary files. Also, "w" and "w+" do not cause truncation of the file; these have affect only when opening a file, and in this case the file has already been opened. You must make sure that the opentype argument matches the actual mode of the open file descriptor.

The return value is the new stream. If the stream cannot be created (for example, if the modes for the file indicated by the file descriptor do not permit the access specified by the *opentype* argument), a null pointer is returned instead.

For an example showing the use of the fdopen function, see Section 14.1 [Creating a Pipe], page 263.

int fileno (FILE *stream)

Function

This function returns the file descriptor associated with the stream stream. If an error is detected (for example, if the stream is not valid) or if stream does not do I/O to a file, fileno returns -1.

There are also symbolic constants defined in 'unistd.h' for the file descriptors belonging to the standard streams stdin, stdout, and stderr; see Section 11.2 [Standard Streams], page 139.

STDIN_FILENO

This macro has value 0, which is the file descriptor for standard input.

STDOUT_FILENO

This macro has value 1, which is the file descriptor for standard output.

STDERR_FILENO

This macro has value 2, which is the file descriptor for standard error output.

12.5 Precautions for Mixing Streams and Descriptors

You can have multiple file descriptors and streams (let's call both streams and descriptors "channels" for short) connected to the same file, but you must take care to avoid confusion between channels. There are two cases to consider: *linked* channels that share a single file position value, and *independent* channels that have their own file positions.

It's best to use just one channel in your program for actual data transfer to any given file, except when all the access is for input. For example, if you open a pipe (something you can only do at the file descriptor level), either do all I/O with the descriptor, or construct a stream from the descriptor with fdopen and then do all I/O with the stream.

12.5.1 Linked Channels

Channels that come from a single opening share the same file position; we call them *linked* channels. Linked channels result when you make a stream from a descriptor using fdopen, when you get a descriptor from a stream with fileno, and when you copy a descriptor with dup or dup2. For files that don't support random access, such as terminals and pipes, *all* channels are effectively linked. On random-access files, all append-type output streams are effectively linked to each other.

If you have been using a stream for I/O, and you want to do I/O using another channel (either a stream or a descriptor) that is linked to it, you must first *clean up* the stream that you have been using. See Section 12.5.3 [Cleaning Streams], page 214.

Terminating a process, or executing a new program in the process, destroys all the streams in the process. If descriptors linked to these streams persist in other processes, their file positions become undefined as a result. To prevent this, you must clean up the streams before destroying them.

214 The GNU C Library

12.5.2 Independent Channels

When you open channels (streams or descriptors) separately on a seekable file, each channel has its own file position. These are called *independent channels*.

The system handles each channel independently. Most of the time, this is quite predictable and natural (especially for input): each channel can read or write sequentially at its own place in the file. The precautions you should take are these:

- You should clean an output stream after use, before doing anything else that might read or write from the same part of the file.
- You should clean an input stream before reading data that may have been modified using an independent channel. Otherwise, you might read obsolete data that had been in the stream's buffer.

If you do output to one channel at the end of the file, this will certainly leave the other independent channels positioned somewhere before the new end. If you want them to output at the end, you must set their file positions to end of file, first. (This is not necessary if you use an append-type descriptor or stream; they always output at the current end of the file.) In order to make the end-of-file position accurate, you must clean the output channel you were using, if it is a stream. (This is necessary even if you plan to use an append-type channel next.)

It's impossible for two channels to have separate file pointers for a file that doesn't support random access. Thus, channels for reading or writing such files are always linked, never independent. Append-type channels are also always linked. For these channels, follow the rules for linked channels; see Section 12.5.1 [Linked Channels], page 213.

12.5.3 Cleaning Streams

On the GNU system, you can clean up any stream with fclean:

int fclean (stream)

Function

Clean up the stream stream so that its buffer is empty. If stream is doing output, force it out. If stream is doing input, give the data in the buffer back to the system, arranging to reread it.

On other systems, you can use fflush to clean a stream in most cases.

You can skip the fclean or fflush if you know the stream is already clean. A stream is clean whenever its buffer is empty. For example, an unbuffered stream is always clean. An input stream that is at end-of-file is clean. A line-buffered stream is clean when the last character output was a newline.

There is one case in which cleaning a stream is impossible on most systems. This is when the stream is doing input from a file that is not random-access. Such streams typically read ahead, and when the file is not random access, there is no way to give back the excess data already read. When an input stream reads from a random-access file, fflush does clean the stream, but leaves the file pointer at an unpredictable place; you must set the file pointer before doing any further I/O. On the GNU system, using fclean avoids both of these problems.

Closing an output-only stream also does fflush, so this is a valid way of cleaning an output stream. On the GNU system, closing an input stream does fclean.

You need not clean a stream before using its descriptor for control operations such as setting terminal modes; these operations don't affect the file position and are not affected by it. You can use any descriptor for these operations, and all channels are affected simultaneously. However, text already "output" to a stream but still buffered by the stream will be subject to the new terminal modes when subsequently flushed. To make sure "past" output is covered by the terminal settings that were in effect at the time, flush the output streams for that terminal before setting the modes. See Section 16.4 [Terminal Modes], page 323.

12.6 Waiting for Input or Output

Sometimes a program needs to accept input on multiple input channels whenever input arrives. For example, some workstations may have devices such as a digitizing tablet, function button box, or dial box that are connected via normal asynchronous serial interfaces; good user interface style requires responding immediately to input on any device. Another example is a program that acts as a server to several other processes via pipes or sockets.

You cannot normally use read for this purpose, because this blocks the program until input is available on one particular file descriptor; input on other channels won't wake it up. You could set nonblocking mode and poll each file descriptor in turn, but this is very inefficient.

216 The GNU C Library

A better solution is to use the **select** function. This blocks the program until input or output is ready on a specified set of file descriptors, or until timer expires, whichever comes first. This facility is declared in the header file 'sys/types.h'.

The file descriptor sets for the select function are specified as fd_set objects. Here is the description of the data type and some macros for manipulating these objects.

fd_set Data Type

The fd_set data type represents file descriptor sets for the select function. It is actually a bit array.

int FD_SETSIZE Macro

The value of this macro is the maximum number of file descriptors that a fd_set object can hold information about. On systems with a fixed maximum number, FD_SETSIZE is at least that number. On some systems, including GNU, there is no absolute limit on the number of descriptors open, but this macro still has a constant value which controls the number of bits in an fd_set.

void FD_ZERO (fd_set *set)

Macro

This macro initializes the file descriptor set set to be the empty set.

void FD_SET (int filedes, fd_set *set)

Macro

This macro adds filedes to the file descriptor set set.

void FD_CLR (int filedes, fd_set *set)

Macro

This macro removes filedes from the file descriptor set set.

int FD_ISSET (int filedes, fd_set *set)

Macro

This macro returns a nonzero value (true) if *filedes* is a member of the the file descriptor set *set*, and zero (false) otherwise.

Next, here is the description of the select function itself.

The select function blocks the calling process until there is activity on any of the specified sets of file descriptors, or until the timeout period has expired.

The file descriptors specified by the read_fds argument are checked to see if they are ready for reading; the write_fds file descriptors are checked to see if they are ready for writing; and the except_fds file descriptors are checked for exceptional conditions. You can pass a null pointer for any of these arguments if you are not interested in checking for that kind of condition.

"Exceptional conditions" does not mean errors—errors are reported immediately when an erroneous system call is executed, and do not constitute a state of the descriptor. Rather, they include conditions such as the presence of an urgent message on a socket. (See Chapter 15 [Sockets], page 269, for information on urgent messages.)

The select function checks only the first *nfds* file descriptors. The usual thing is to pass FD_SETSIZE as the value of this argument.

The timeout specifies the maximum time to wait. If you pass a null pointer for this argument, it means to block indefinitely until one of the file descriptors is ready. Otherwise, you should provide the time in struct timeval format; see Section 19.2.2 [High-Resolution Calendar], page 375. Specify zero as the time (a struct timeval containing all zeros) if you want to find out which descriptors are ready without waiting if none are ready.

The normal return value from select is the total number of ready file descriptors in all of the sets. Each of the argument sets is overwritten with information about the descriptors that are ready for the corresponding operation. Thus, to see if a particular descriptor desc has input, use FD_ISSET (desc, read fds) after select returns.

If select returns because the timeout period expires, it returns a value of zero.

Any signal will cause select to return immediately. So if your program uses signals, you can't rely on select to keep waiting for the full time specified. If you want to be sure of waiting for a particular amount of time, you must check for EINTR and repeat the select with a newly calculated timeout based on the current time. See the example below. See also Section 21.5 [Interrupted Primitives], page 438.

If an error occurs, select returns -1 and does not modify the argument file descriptor sets. The following error conditions are defined for this function:

EBADF One of the file descriptor sets specified an invalid file descriptor.

```
EINTR The operation was interrupted by a signal. See Section 21.5 [Interrupted Primitives], page 438.

EINVAL The timeout argument is invalid; one of the components is negative or too large.
```

Portability Note: The select function is a BSD Unix feature.

Here is an example showing how you can use **select** to establish a timeout period for reading from a file descriptor. The **input_timeout** function blocks the calling process until input is available on the file descriptor, or until the timeout period expires.

```
#include <stdio.h>
#include <unistd.h>
#include <sys/types.h>
#include <sys/time.h>
input_timeout (int filedes, unsigned int seconds)
  fd_set set;
  struct timeval timeout;
  /* Initialize the file descriptor set. */
  FD_ZERO (&set);
  FD_SET (filedes, &set);
  /* Initialize the timeout data structure. */
  timeout.tv_sec = seconds;
  timeout.tv_usec = 0;
  /* select returns 0 if timeout, 1 if input available, -1 if error. */
  return TEMP_FAILURE_RETRY (select (FD_SETSIZE, &set, NULL, NULL, &timeout));
}
int
main (void)
  fprintf (stderr, "select returned %d.\n", input_timeout (STDIN_FILENO, 5));
  return 0;
}
```

There is another example showing the use of select to multiplex input from multiple sockets in Section 15.8.7 [Server Example], page 303.

12.7 Control Operations on Files

This section describes how you can perform various other operations on file descriptors, such as inquiring about or setting flags describing the status of the file descriptor, manipulating record locks, and the like. All of these operations are performed by the function fcntl.

The second argument to the fcntl function is a command that specifies which operation to perform. The function and macros that name various flags that are used with it are declared in the header file 'fcntl.h'. (Many of these flags are also used by the open function; see Section 12.1 [Opening and Closing Files], page 203.)

int fcntl (int filedes, int command, ...)

Function

The fcntl function performs the operation specified by command on the file descriptor filedes. Some commands require additional arguments to be supplied. These additional arguments and the return value and error conditions are given in the detailed descriptions of the individual commands.

Briefly, here is a list of what the various commands are.

- F_DUPFD Duplicate the file descriptor (return another file descriptor pointing to the same open file). See Section 12.8 [Duplicating Descriptors], page 220.
- F_GETFD Get flags associated with the file descriptor. See Section 12.9 [Descriptor Flags], page 222.
- F_SETFD Set flags associated with the file descriptor. See Section 12.9 [Descriptor Flags], page 222.
- F_GETFL Get flags associated with the open file. See Section 12.10 [File Status Flags], page 224.
- F_SETFL Set flags associated with the open file. See Section 12.10 [File Status Flags], page 224.
- F_GETLK Get a file lock. See Section 12.11 [File Locks], page 226.
- F_SETLK Set or clear a file lock. See Section 12.11 [File Locks], page 226.
- F_SETLKW Like F_SETLK, but wait for completion. See Section 12.11 [File Locks], page 226.
- F_GETOWN Get process or process group ID to receive SIGIO signals. See Section 12.12 [Interrupt Input], page 231.
- F_SETOWN Set process or process group ID to receive SIGIO signals. See Section 12.12 [Interrupt Input], page 231.

12.8 Duplicating Descriptors

You can duplicate a file descriptor, or allocate another file descriptor that refers to the same open file as the original. Duplicate descriptors share one file position and one set of file status flags (see Section 12.10 [File Status Flags], page 224), but each has its own set of file descriptor flags (see Section 12.9 [Descriptor Flags], page 222).

The major use of duplicating a file descriptor is to implement redirection of input or output: that is, to change the file or pipe that a particular file descriptor corresponds to.

You can perform this operation using the fcntl function with the F_DUPFD command, but there are also convenient functions dup and dup2 for duplicating descriptors.

The fcntl function and flags are declared in 'fcntl.h', while prototypes for dup and dup2 are in the header file 'unistd.h'.

```
int dup (int old) Function
```

This function copies descriptor old to the first available descriptor number (the first number not currently open). It is equivalent to fcntl (old, F_DUPFD, 0).

```
int dup2 (int old, int new)
```

Function

This function copies the descriptor old to descriptor number new.

If old is an invalid descriptor, then dup2 does nothing; it does not close new. Otherwise, the new duplicate of old replaces any previous meaning of descriptor new, as if new were closed first.

If old and new are different numbers, and old is a valid descriptor number, then dup2 is equivalent to:

```
close (new);
fcntl (old, F_DUPFD, new)
```

However, dup2 does this atomically; there is no instant in the middle of calling dup2 at which new is closed and not yet a duplicate of old.

int F_DUPFD Macro

This macro is used as the *command* argument to fcnt1, to copy the file descriptor given as the first argument.

The form of the call in this case is:

```
fcntl (old, F_DUPFD, next_filedes)
```

The next_filedes argument is of type int and specifies that the file descriptor returned should be the next available one greater than or equal to this value.

The return value from fcntl with this command is normally the value of the new file descriptor. A return value of -1 indicates an error. The following errno error conditions are defined for this command:

EBADF The old argument is invalid.

EINVAL The next_filedes argument is invalid.

EMFILE There are no more file descriptors available—your program is already using

the maximum.

ENFILE is not a possible error code for dup2 because dup2 does not create a new opening of a file; duplicate descriptors do not count toward the limit which ENFILE indicates. EMFILE is possible because it refers to the limit on distinct descriptor numbers in use in one process.

Here is an example showing how to use dup2 to do redirection. Typically, redirection of the standard streams (like stdin) is done by a shell or shell-like program before calling one of the exec functions (see Section 23.5 [Executing a File], page 485) to execute a new program in a child process. When the new program is executed, it creates and initializes the standard streams to point to the corresponding file descriptors, before its main function is invoked.

So, to redirect standard input to a file, the shell could do something like:

```
pid = fork ();
```

```
if (pid == 0)
{
   char *filename;
   char *program;
   int file;
   ...
   file = TEMP_FAILURE_RETRY (open (filename, O_RDONLY));
   dup2 (file, STDIN_FILENO);
   TEMP_FAILURE_RETRY (close (file));
   execv (program, NULL);
}
```

There is also a more detailed example showing how to implement redirection in the context of a pipeline of processes in Section 24.6.3 [Launching Jobs], page 503.

12.9 File Descriptor Flags

File descriptor flags are miscellaneous attributes of a file descriptor. These flags are associated with particular file descriptors, so that if you have created duplicate file descriptors from a single opening of a file, each descriptor has its own set of flags.

Currently there is just one file descriptor flag: FD_CLOEXEC, which causes the descriptor to be closed if you use any of the exec... functions (see Section 23.5 [Executing a File], page 485).

The symbols in this section are defined in the header file 'fcntl.h'.

int F_GETFD Macro

This macro is used as the *command* argument to fcnt1, to specify that it should return the file descriptor flags associated with the *filedes* argument.

The normal return value from fcntl with this command is a nonnegative number which can be interpreted as the bitwise OR of the individual flags (except that currently there is only one flag to use).

In case of an error, fcntl returns -1. The following errno error conditions are defined for this command:

EBADF The filedes argument is invalid.

int F_SETFD Macro

This macro is used as the *command* argument to fcntl, to specify that it should set the file descriptor flags associated with the *filedes* argument. This requires a third int argument to specify the new flags, so the form of the call is:

```
fcntl (filedes, F_SETFD, new_flags)
```

The normal return value from fcntl with this command is an unspecified value other than -1, which indicates an error. The flags and error conditions are the same as for the F_GETFD command.

The following macro is defined for use as a file descriptor flag with the fcntl function. The value is an integer constant usable as a bit mask value.

int FD_CLOEXEC Macro

This flag specifies that the file descriptor should be closed when an exec function is invoked; see Section 23.5 [Executing a File], page 485. When a file descriptor is allocated (as with open or dup), this bit is initially cleared on the new file descriptor, meaning that descriptor will survive into the new program after exec.

If you want to modify the file descriptor flags, you should get the current flags with F_GETFD and modify the value. Don't assume that the flag listed here is the only ones that are implemented; your program may be run years from now and more flags may exist then. For example, here is a function to set or clear the flag FD_CLOEXEC without altering any other flags:

```
/* Set the FD_CLOEXEC flag of desc if value is nonzero,
    or clear the flag if value is 0.
    Return 0 on success, or -1 on error with errno set. */
int
set_cloexec_flag (int desc, int value)
```

```
int oldflags = fcntl (desc, F_GETFD, 0);
/* If reading the flags failed, return error indication now.
if (oldflags < 0)
    return oldflags;
/* Set just the flag we want to set. */
if (value != 0)
    oldflags |= FD_CLOEXEC;
else
    oldflags &= ~FD_CLOEXEC;
/* Store modified flag word in the descriptor. */
    return fcntl (desc, F_SETFD, oldflags);
}</pre>
```

12.10 File Status Flags

File status flags are used to specify attributes of the opening of a file. Unlike the file descriptor flags discussed in Section 12.9 [Descriptor Flags], page 222, the file status flags are shared by duplicated file descriptors resulting from a single opening of the file.

The file status flags are initialized by the open function from the flags argument of the open function. Some of the flags are meaningful only in open and are not remembered subsequently; many of the rest cannot subsequently be changed, though you can read their values by examining the file status flags.

A few file status flags can be changed at any time using fcntl. These include O_APPEND and $O_NONBLOCK$.

The symbols in this section are defined in the header file 'fcntl.h'.

int F_GETFL Macro

This macro is used as the *command* argument to **fcnt1**, to read the file status flags for the open file with descriptor filedes.

The normal return value from fcntl with this command is a nonnegative number which can be interpreted as the bitwise OR of the individual flags. The flags are encoded like the flags argument to open (see Section 12.1 [Opening and Closing Files], page 203), but only the file access modes and the O_APPEND and O_NONBLOCK flags are meaningful here. Since the file access modes are not single-bit values, you can mask off other bits in the returned flags with O_ACCMODE to compare them.

In case of an error, fcntl returns -1. The following error conditions are defined for this command:

EBADF The filedes argument is invalid.

int F_SETFL Macro

This macro is used as the *command* argument to fcnt1, to set the file status flags for the open file corresponding to the *filedes* argument. This command requires a third int argument to specify the new flags, so the call looks like this:

fcntl (filedes, F_SETFL, new_flags)

You can't change the access mode for the file in this way; that is, whether the file descriptor was opened for reading or writing. You can only change the O_APPEND and $O_NONBLOCK$ flags.

The normal return value from fcntl with this command is an unspecified value other than -1, which indicates an error. The error conditions are the same as for the F_GETFL command.

The following macros are defined for use in analyzing and constructing file status flag values:

O_APPEND The bit that enables append mode for the file. If set, then all write operations write the data at the end of the file, extending it, regardless of the current file position.

O_NONBLOCK

The bit that enables nonblocking mode for the file. If this bit is set, read requests on the file can return immediately with a failure status if there is no input immediately available, instead of blocking. Likewise, write requests can also return immediately with a failure status if the output can't be written immediately.

O_NDELAY This is a synonym for O_NONBLOCK, provided for compatibility with BSD.

int O_ACCMODE Macro

This macro stands for a mask that can be bitwise-ANDed with the file status flag value to produce a value representing the file access mode. The mode will be O_RDONLY, O_WRONLY, or O_RDWR.

```
O_RDONLY Open the file for read access.O_WRONLY Open the file for write access.O_RDWR Open the file for both reading and writing.
```

If you want to modify the file status flags, you should get the current flags with F_GETFL and modify the value. Don't assume that the flags listed here are the only ones that are implemented; your program may be run years from now and more flags may exist then. For example, here is a function to set or clear the flag O_NONBLOCK without altering any other flags:

```
/* Set the O_NONBLOCK flag of desc if value is nonzero,
   or clear the flag if value is 0.
   Return 0 on success, or -1 on error with errno set. */
int
set_nonblock_flag (int desc, int value)
  int oldflags = fcntl (desc, F_GETFL, 0);
  /* If reading the flags failed, return error indication now. */
  if (oldflags < 0)
    return oldflags;
  /* Set just the flag we want to set. */
  if (value != 0)
    oldflags |= O_NONBLOCK;
    oldflags &= ~O_NONBLOCK;
  /* Store modified flag word in the descriptor. */
  return fcntl (desc, F_SETFL, oldflags);
}
```

12.11 File Locks

The remaining fcnt1 commands are used to support record locking, which permits multiple cooperating programs to prevent each other from simultaneously accessing parts of a file in error-prone ways.

An exclusive or write lock gives a process exclusive access for writing to the specified part of the file. While a write lock is in place, no other process can lock that part of the file.

A shared or read lock prohibits any other process from requesting a write lock on the specified part of the file. However, other processes can request read locks.

The read and write functions do not actually check to see whether there are any locks in place. If you want to implement a locking protocol for a file shared by multiple processes, your application must do explicit fcntl calls to request and clear locks at the appropriate points.

Locks are associated with processes. A process can only have one kind of lock set for each byte of a given file. When any file descriptor for that file is closed by the process, all of the locks that process holds on that file are released, even if the locks were made using other descriptors that remain open. Likewise, locks are released when a process exits, and are not inherited by child processes created using fork (see Section 23.4 [Creating a Process], page 483).

When making a lock, use a struct flock to specify what kind of lock and where. This data type and the associated macros for the fcntl function are declared in the header file 'fcntl.h'.

flock struct Type

This structure is used with the fcntl function to describe a file lock. It has these members:

short int l_type

Specifies the type of the lock; one of F_RDLCK, F_WRLCK, or F_UNLCK.

short int l_whence

This corresponds to the *whence* argument to fseek or lseek, and specifies what the offset is relative to. Its value can be one of SEEK_SET, SEEK_CUR, or SEEK_END.

off_t l_start

This specifies the offset of the start of the region to which the lock applies, and is given in bytes relative to the point specified by 1_whence member.

off_t l_len

This specifies the length of the region to be locked. A value of 0 is treated specially; it means the region extends to the end of the file.

pid_t l_pid

This field is the process ID (see Section 23.2 [Process Creation Concepts], page 482) of the process holding the lock. It is filled in by calling fcntl with the F_GETLK command, but is ignored when making a lock.

int F_GETLK Macro

This macro is used as the *command* argument to fcntl, to specify that it should get information about a lock. This command requires a third argument of type struct flock * to be passed to fcntl, so that the form of the call is:

fcntl (filedes, F_GETLK, lockp)

If there is a lock already in place that would block the lock described by the *lockp* argument, information about that lock overwrites **lockp*. Existing locks are not reported if they are compatible with making a new lock as specified. Thus, you should specify a lock type of F_WRLCK if you want to find out about both read and write locks, or F_RDLCK if you want to find out about write locks only.

There might be more than one lock affecting the region specified by the *lockp* argument, but fcntl only returns information about one of them. The 1_whence member of the *lockp* structure is set to SEEK_SET and the 1_start and 1_len fields set to identify the locked region.

If no lock applies, the only change to the *lockp* structure is to update the 1_type to a value of F_UNLCK.

The normal return value from fcntl with this command is an unspecified value other than -1, which is reserved to indicate an error. The following errno error conditions are defined for this command:

EBADF The filedes argument is invalid.

EINVAL Either the *lockp* argument doesn't specify valid lock information, or the file associated with *filedes* doesn't support locks.

int F_SETLK Macro

This macro is used as the *command* argument to fcntl, to specify that it should set or clear a lock. This command requires a third argument of type struct flock * to be passed to fcntl, so that the form of the call is:

fcntl (filedes, F_SETLK, lockp)

If the process already has a lock on any part of the region, the old lock on that part is replaced with the new lock. You can remove a lock by specifying the a lock type of F_UNLCK .

If the lock cannot be set, fcntl returns immediately with a value of -1. This function does not block waiting for other processes to release locks. If fcntl succeeds, it return a value other than -1.

The following errno error conditions are defined for this function:

EACCES

EAGAIN The lock cannot be set because it is blocked by an existing lock on the file. Some systems use EAGAIN in this case, and other systems use EACCES; your program should treat them alike, after F_SETLK.

EBADF Either: the *filedes* argument is invalid; you requested a read lock but the *filedes* is not open for read access; or, you requested a write lock but the *filedes* is not open for write access.

EINVAL Either the *lockp* argument doesn't specify valid lock information, or the file associated with *filedes* doesn't support locks.

ENOLCK The system has run out of file lock resources; there are already too many file locks in place.

Well-designed file systems never report this error, because they have no limitation on the number of locks. However, you must still take account of the possibility of this error, as it could result from network access to a file system on another machine.

int F_SETLKW Macro

This macro is used as the *command* argument to fcntl, to specify that it should set or clear a lock. It is just like the F_SETLK command, but causes the process to block (or wait) until the request can be specified.

This command requires a third argument of type struct flock *, as for the F_SETLK command.

The fcntl return values and errors are the same as for the F_SETLK command, but these additional error conditions are defined for this command:

EINTR The function was interrupted by a signal while it was waiting. See Section 21.5 [Interrupted Primitives], page 438.

EDEADLK A deadlock condition was detected. This can happen if two processes each already controlling a locked region request a lock on the same region locked by the other process.

The following macros are defined for use as values for the l_type member of the flock structure. The values are integer constants.

F_RDLCK This macro is used to specify a read (or shared) lock.

F_WRLCK This macro is used to specify a write (or exclusive) lock.

F_UNLCK This macro is used to specify that the region is unlocked.

As an example of a situation where file locking is useful, consider a program that can be run simultaneously by several different users, that logs status information to a common file. One example of such a program might be a game that uses a file to keep track of high scores. Another example might be a program that records usage or accounting information for billing purposes.

Having multiple copies of the program simultaneously writing to the file could cause the contents of the file to become mixed up. But you can prevent this kind of problem by setting a write lock on the file before actually writing to the file.

If the program also needs to read the file and wants to make sure that the contents of the file are in a consistent state, then it can also use a read lock. While the read lock is set, no other process can lock that part of the file for writing.

Remember that file locks are only a *voluntary* protocol for controlling access to a file. There is still potential for access to the file by programs that don't use the lock protocol.

12.12 Interrupt-Driven Input

If you set the FASYNC status flag on a file descriptor (see Section 12.10 [File Status Flags], page 224), a SIGIO signal is sent whenever input or output becomes possible on that file descriptor. The process or process group to receive the signal can be selected by using the F_SETOWN command to the fcntl function. If the file descriptor is a socket, this also selects the recipient of SIGURG signals that are delivered when out-of-band data arrives on that socket; see Section 15.8.8 [Out-of-Band Data], page 306.

If the file descriptor corresponds to a terminal device, then SIGIO signals are sent to the foreground process group of the terminal. See Chapter 24 [Job Control], page 495.

The symbols in this section are defined in the header file 'fcntl.h'.

int F_GETOWN Macro

This macro is used as the *command* argument to fcnt1, to specify that it should get information about the process or process group to which SIGIO signals are sent. (For a terminal, this is actually the foreground process group ID, which you can get using tcgetpgrp; see Section 24.7.3 [Terminal Access Functions], page 518.)

The return value is interpreted as a process ID; if negative, its absolute value is the process group ID.

The following errno error condition is defined for this command:

EBADF The filedes argument is invalid.

int F_SETOWN Macro

This macro is used as the *command* argument to fcntl, to specify that it should set the process or process group to which SIGIO signals are sent. This command requires a third argument of type pid_t to be passed to fcntl, so that the form of the call is:

fcntl (filedes, F_SETOWN, pid)

The pid argument should be a process ID. You can also pass a negative number whose absolute value is a process group ID.

The return value from fcntl with this command is -1 in case of error and some other value if successful. The following error conditions are defined for this command:

EBADF The filedes argument is invalid.

ESRCH There is no process or process group corresponding to pid.

13 File System Interface

This chapter describes the GNU C library's functions for manipulating files. Unlike the input and output functions described in Chapter 11 [I/O on Streams], page 139 and Chapter 12 [Low-Level I/O], page 203, these functions are concerned with operating on the files themselves, rather than on their contents.

Among the facilities described in this chapter are functions for examining or modifying directories, functions for renaming and deleting files, and functions for examining and setting file attributes such as access permissions and modification times.

13.1 Working Directory

Each process has associated with it a directory, called its *current working directory* or simply working directory, that is used in the resolution of relative file names (see Section 10.2.2 [File Name Resolution], page 135).

When you log in and begin a new session, your working directory is initially set to the home directory associated with your login account in the system user database. You can find any user's home directory using the getpwuid or getpwnam functions; see Section 25.12 [User Database], page 533.

Users can change the working directory using shell commands like cd. The functions described in this section are the primitives used by those commands and by other programs for examining and changing the working directory.

Prototypes for these functions are declared in the header file 'unistd.h'.

char * getcwd (char *buffer, size_t size)

Function

The getcwd function returns an absolute file name representing the current working directory, storing it in the character array buffer that you provide. The size argument is how you tell the system the allocation size of buffer.

The GNU library version of this function also permits you to specify a null pointer for the buffer argument. Then getcwd allocates a buffer automatically, as with malloc (see Section 3.3 [Unconstrained Allocation], page 30). If the size is greater than zero,

then the buffer is that large; otherwise, the buffer is as large as necessary to hold the result.

The return value is *buffer* on success and a null pointer on failure. The following **errno** error conditions are defined for this function:

EINVAL The size argument is zero and buffer is not a null pointer.

ERANGE The size argument is less than the length of the working directory name. You need to allocate a bigger array and try again.

EACCES Permission to read or search a component of the file name was denied.

Here is an example showing how you could implement the behavior of GNU's getcwd (NULL, 0) using only the standard behavior of getcwd:

```
char *
gnu_getcwd ()
{
  int size = 100;
  char *buffer = (char *) xmalloc (size);

  while (1)
    {
      char *value = getcwd (buffer, size);
      if (value != 0)
          return buffer;
      size *= 2;
      free (buffer);
      buffer = (char *) xmalloc (size);
    }
}
```

See Section 3.3.2 [Malloc Examples], page 32, for information about xmalloc, which is not a library function but is a customary name used in most GNU software.

```
char * getwd (char *buffer)
```

Function

This is similar to getcwd. The GNU library provides getwd for backwards compatibility with BSD. The buffer should be a pointer to an array at least PATH_MAX bytes long.

int chdir (const char *filename)

Function

This function is used to set the process's working directory to filename.

The normal, successful return value from chdir is 0. A value of -1 is returned to indicate an error. The error conditions defined for this function are the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), plus ENOTDIR if the file filename is not a directory.

13.2 Accessing Directories

The facilities described in this section let you read the contents of a directory file. This is useful if you want your program to list all the files in a directory, perhaps as part of a menu.

The opendir function opens a directory stream whose elements are directory entries. You use the readdir function on the directory stream to retrieve these entries, represented as struct dirent objects. The name of the file for each entry is stored in the d_name member of this structure. There are obvious parallels here to the stream facilities for ordinary files, described in Chapter 11 [I/O on Streams], page 139.

13.2.1 Format of a Directory Entry

This section describes what you find in a single directory entry, as you might obtain it from a directory stream. All the symbols are declared in the header file 'direct.h'.

struct dirent Data Type

This is a structure type used to return information about directory entries. It contains the following fields:

char *d_name

This is the null-terminated file name component. This is the only field you can count on in all POSIX systems.

ino_t d_fileno

This is the file serial number. For BSD compatibility, you can also refer to this member as d_ino.

size_t d_namlen

This is the length of the file name, not including the terminating null character.

This structure may contain additional members in the future.

When a file has multiple names, each name has its own directory entry. The only way you can tell that the directory entries belong to a single file is that they have the same value for the d_fileno field.

File attributes such as size, modification times, and the like are part of the file itself, not any particular directory entry. See Section 13.8 [File Attributes], page 246.

13.2.2 Opening a Directory Stream

This section describes how to open a directory stream. All the symbols are declared in the header file 'dirent.h'.

DIR Data Type

The DIR data type represents a directory stream.

You shouldn't ever allocate objects of the struct direct or DIR data types, since the directory access functions do that for you. Instead, you refer to these objects using the pointers returned by the following functions.

DIR * opendir (const char *dirname)

Function

The opendir function opens and returns a directory stream for reading the directory whose file name is dirname. The stream has type DIR *.

If unsuccessful, opendir returns a null pointer. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following error conditions are defined for this function:

EACCES Read permission is denied for the directory named by dirname.

EMFILE The process has too many files open.

ENFILE The entire system, or perhaps the file system which contains the directory, cannot support any additional open files at the moment. (This problem cannot happen on the GNU system.)

The DIR type is typically implemented using a file descriptor, and the opendir function in terms of the open function. See Chapter 12 [Low-Level I/O], page 203. Directory streams and the underlying file descriptors are closed on exec (see Section 23.5 [Executing a File], page 485).

13.2.3 Reading and Closing a Directory Stream

This section describes how to read directory entries from a directory stream, and how to close the stream when you are done with it. All the symbols are declared in the header file 'dirent.h'.

struct dirent * readdir (DIR *dirstream)

Function

This function reads the next entry from the directory. It normally returns a pointer to a structure containing information about the file. This structure is statically allocated and can be rewritten by a subsequent call.

Portability Note: On some systems, readdir may not return entries for '.' and '..'. See Section 10.2.2 [File Name Resolution], page 135.

If there are no more entries in the directory or an error is detected, readdir returns a null pointer. The following error conditions are defined for this function:

EBADF The dirstream argument is not valid.

int closedir (DIR *dirstream)

Function

This function closes the directory stream directory. It returns 0 on success and -1 on failure.

The following errno error conditions are defined for this function:

EBADF The dirstream argument is not valid.

13.2.4 Simple Program to List a Directory

Here's a simple program that prints the names of the files in the current working directory:

```
#include <stddef.h>
#include <stdio.h>
#include <sys/types.h>
#include <dirent.h>
int
main (void)
 DIR *dp;
  struct dirent *ep;
  dp = opendir ("./");
  if (dp != NULL)
      while (ep = readdir (dp))
puts (ep->d_name);
      (void) closedir (dp);
    }
    puts ("Couldn't open the directory.");
 return 0;
}
```

The order in which files appear in a directory tends to be fairly random. A more useful program would sort the entries (perhaps by alphabetizing them) before printing them; see Section 8.3 [Array Sort Function], page 108

13.2.5 Random Access in a Directory Stream

This section describes how to reread parts of a directory that you have already read from an open directory stream. All the symbols are declared in the header file 'direct.h'.

void rewinddir (DIR *dirstream)

Function

The rewinddir function is used to reinitialize the directory stream directory, so that if you call readdir it returns information about the first entry in the directory again. This function also notices if files have been added or removed to the directory since it

was opened with opendir. (Entries for these files might or might not be returned by readdir if they were added or removed since you last called opendir or rewinddir.)

off_t telldir (DIR *dirstream)

Function

The telldir function returns the file position of the directory stream directory. You can use this value with seekdir to restore the directory stream to that position.

void seekdir (DIR *dirstream, off_t pos)

Function

The seekdir function sets the file position of the directory stream directorm to pos. The value pos must be the result of a previous call to telldir on this particular stream; closing and reopening the directory can invalidate values returned by telldir.

13.3 Hard Links

In POSIX systems, one file can have many names at the same time. All of the names are equally real, and no one of them is preferred to the others.

To add a name to a file, use the link function. (The new name is also called a hard link to the file.) Creating a new link to a file does not copy the contents of the file; it simply makes a new name by which the file can be known, in addition to the file's existing name or names.

One file can have names in several directories, so the the organization of the file system is not a strict hierarchy or tree.

Since a particular file exists within a single file system, all its names must be in directories in that file system. link reports an error if you try to make a hard link to the file from another file system.

The prototype for the link function is declared in the header file 'unistd.h'.

int link (const char *oldname, const char *newname)

Function

The link function makes a new link to the existing file named by *oldname*, under the new name *newname*.

This function returns a value of 0 if it is successful and -1 on failure. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136) for

both *oldname* and *newname*, the following errno error conditions are defined for this function:

EACCES The directory in which the new link is to be written is not writable.

EEXIST There is already a file named *newname*. If you want to replace this link with a new link, you must remove the old link explicitly first.

EMLINK There are already too many links to the file named by *oldname*. (The maximum number of links to a file is LINK_MAX; see Section 27.6 [Limits for Files], page 553.)

Well-designed file systems never report this error, because they permit more links than your disk could possibly hold. However, you must still take account of the possibility of this error, as it could result from network access to a file system on another machine.

ENOENT The file named by *oldname* doesn't exist. You can't make a link to a file that doesn't exist.

ENOSPC The directory or file system that would contain the new link is "full" and cannot be extended.

EPERM Some implementations only allow privileged users to make links to directories, and others prohibit this operation entirely. This error is used to report the problem.

EROFS The directory containing the new link can't be modified because it's on a read-only file system.

EXDEV The directory specified in *newname* is on a different file system than the existing file.

13.4 Symbolic Links

The GNU system supports soft links or symbolic links. This is a kind of "file" that is essentially a pointer to another file name. Unlike hard links, symbolic links can be made to directories or across file systems with no restrictions. You can also make a symbolic link to a name which is not the name of any file. (Opening this link will fail until a file by that name is created.) Likewise, if the symbolic link points to an existing file which is later deleted, the symbolic link continues to point to the same file name even though the name no longer names any file.

The reason symbolic links work the way they do is that special things happen when you try to open the link. The open function realizes you have specified the name of a link, reads the file name contained in the link, and opens that file name instead. The stat function likewise operates on the

file that the symbolic link points to, instead of on the link itself. So does link, the function that makes a hard link.

By contrast, other operations such as deleting or renaming the file operate on the link itself. The functions readlink and lstat also refrain from following symbolic links, because their purpose is to obtain information about the link.

Prototypes for the functions listed in this section are in 'unistd.h'.

```
int symlink (const char *oldname, const char *newname)
```

Function

The symlink function makes a symbolic link to oldname named newname.

The normal return value from symlink is 0. A return value of -1 indicates an error. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following error conditions are defined for this function:

EEXIST There is already an existing file named newname.

EROFS The file newname would exist on a read-only file system.

ENOSPC The directory or file system cannot be extended to make the new link.

EIO A hardware error occurred while reading or writing data on the disk.

int readlink (const char *filename, char *buffer, size_t size)

Function

The readlink function gets the value of the symbolic link filename. The file name that the link points to is copied into buffer. This file name string is not null-terminated; readlink normally returns the number of characters copied. The size argument specifies the maximum number of characters to copy, usually the allocation size of buffer.

If the return value equals size, you cannot tell whether or not there was room to return the entire name. So make a bigger buffer and call readlink again. Here is an example:

```
char *
readlink_malloc (char *filename)
{
  int size = 100;
```

```
while (1)
    {
      char *buffer = (char *) xmalloc (size);
      int nchars = readlink (filename, buffer, size);
      if (nchars < size)
          return buffer;
      free (buffer);
      size *= 2;
    }
}</pre>
```

A value of -1 is returned in case of error. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following errno error conditions are defined for this function:

EINVAL The named file is not a symbolic link.

EIO A hardware error occurred while reading or writing data on the disk.

13.5 Deleting Files

You can delete a file with the functions unlink or remove. (These names are synonymous.)

Deletion actually deletes a file name. If this is the file's only name, then the file is deleted as well. If the file has other names as well (see Section 13.3 [Hard Links], page 239), it remains accessible under its other names.

int unlink (const char *filename)

Function

The unlink function deletes the file name filename. If this is a file's sole name, the file itself is also deleted. (Actually, if any process has the file open when this happens, deletion is postponed until all processes have closed the file.)

The function unlink is declared in the header file 'unistd.h'.

This function returns 0 on successful completion, and -1 on error. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following error conditions are defined for this function:

EACCESS Write permission is denied for the directory from which the file is to be

removed.

EBUSY This error indicates that the file is being used by the system in such a way

that it can't be unlinked. Examples of situations where you might see this error are if the file name specifies the root directory or a mount point for

a file system.

ENOENT The file name to be deleted doesn't exist.

EPERM On some systems, unlink cannot be used to delete the name of a directory,

or can only be used this way by a privileged user. To avoid such problems,

use rmdir to delete directories.

EROFS The directory in which the file name is to be deleted is on a read-only file

system, and can't be modified.

int remove (const char *filename)

Function

The remove function is another name for unlink. remove is the ANSI C name, whereas unlink is the POSIX.1 name. The name remove is declared in 'stdio.h'.

int rmdir (const char *filename)

Function

The rmdir function deletes a directory. The directory must be empty before it can be removed; in other words, it can only contain entries for '.' and '..'.

In most other respects, rmdir behaves like unlink. There are two additional errno error conditions defined for rmdir:

EEXIST

ENOTEMPTY

The directory to be deleted is not empty.

These two error codes are synonymous; some systems use one, and some use the other.

The prototype for this function is declared in the header file 'unistd.h'.

13.6 Renaming Files

The rename function is used to change a file's name.

int rename (const char *oldname, const char *newname)

Function

The rename function renames the file name oldname with newname. The file formerly accessible under the name oldname is afterward accessible as newname instead. (If the file had any other names aside from oldname, it continues to have those names.)

The directory containing the name newname must be on the same file system as the file (as indicated by the name oldname).

One special case for rename is when oldname and newname are two names for the same file. The consistent way to handle this case is to delete oldname. However, POSIX says that in this case rename does nothing and reports success—which is inconsistent. We don't know what your operating system will do. The GNU system, when completed, will probably do the right thing (delete oldname) unless you explicitly request strict POSIX compatibility "even when it hurts".

If the *oldname* is not a directory, then any existing file named *newname* is removed during the renaming operation. However, if *newname* is the name of a directory, **rename** fails in this case.

If the *oldname* is a directory, then either *newname* must not exist or it must name a directory that is empty. In the latter case, the existing directory named *newname* is deleted first. The name *newname* must not specify a subdirectory of the directory oldname which is being renamed.

One useful feature of **rename** is that the meaning of the name *newname* changes "atomically" from any previously existing file by that name to its new meaning (the file that was called *oldname*). There is no instant at which *newname* is nonexistent "in between" the old meaning and the new meaning.

If rename fails, it returns -1. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following error conditions are defined for this function:

EACCES One of the directories containing newname or oldname refuses write per-

mission; or newname and oldname are directories and write permission is

refused for one of them.

EBUSY A directory named by oldname or newname is being used by the system in

a way that prevents the renaming from working. This includes directories that are mount points for filesystems, and directories that are the current

working directories of processes.

EEXIST The directory newname isn't empty.

ENOTEMPTY

The directory newname isn't empty.

EINVAL The oldname is a directory that contains newname.

EISDIR The newname names a directory, but the oldname doesn't.

EMLINK The parent directory of newname would have too many links.

Well-designed file systems never report this error, because they permit more links than your disk could possibly hold. However, you must still take account of the possibility of this error, as it could result from network

access to a file system on another machine.

ENOENT The file named by oldname doesn't exist.

ENOSPC The directory that would contain newname has no room for another entry,

and there is no space left in the file system to expand it.

EROFS The operation would involve writing to a directory on a read-only file sys-

tem.

EXDEV The two file names newname and oldnames are on different file systems.

13.7 Creating Directories

Directories are created with the mkdir function. (There is also a shell command mkdir which does the same thing.)

int mkdir (const char *filename, mode_t mode)

Function

The mkdir function creates a new, empty directory whose name is filename.

The argument *mode* specifies the file permissions for the new directory file. See Section 13.8.5 [Permission Bits], page 253, for more information about this.

A return value of 0 indicates successful completion, and -1 indicates failure. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following error conditions are defined for this function:

EACCES Write permission is denied for the parent directory in which the new directory is to be added.

EEXIST A file named filename already exists.

EMLINK The parent directory has too many links.

Well-designed file systems never report this error, because they permit more links than your disk could possibly hold. However, you must still take account of the possibility of this error, as it could result from network access to a file system on another machine.

ENOSPC The file system doesn't have enough room to create the new directory.

EROFS The parent directory of the directory being created is on a read-only file

system, and cannot be modified.

To use this function, your program should include the header file 'sys/stat.h'.

13.8 File Attributes

When you issue an '1s -1' shell command on a file, it gives you information about the size of the file, who owns it, when it was last modified, and the like. This kind of information is called the *file attributes*; it is associated with the file itself and not a particular one of its names.

This section contains information about how you can inquire about and modify these attributes of files.

13.8.1 What the File Attribute Values Mean

When you read the attributes of a file, they come back in a structure called **struct stat**. This section describes the names of the attributes, their data types, and what they mean. For the functions to read the attributes of a file, see Section 13.8.2 [Reading Attributes], page 249.

The header file 'sys/stat.h' declares all the symbols defined in this section.

struct stat Data Type

The **stat** structure type is used to return information about the attributes of a file. It contains at least the following members:

mode_t st_mode

Specifies the mode of the file. This includes file type information (see Section 13.8.3 [Testing File Type], page 250) and the file permission bits (see Section 13.8.5 [Permission Bits], page 253).

ino_t st_ino

The file serial number, which distinguishes this file from all other files on the same device.

dev_t st_dev

Identifies the device containing the file. The st_ino and st_dev, taken together, uniquely identify the file.

nlink_t st_nlink

The number of hard links to the file. This count keeps track of how many directories have entries for this file. If the count is ever decremented to zero, then the file itself is discarded. Symbolic links are not counted in the total.

uid_t st_uid

The user ID of the file's owner. See Section 13.8.4 [File Owner], page 252.

gid_t st_gid

The group ID of the file. See Section 13.8.4 [File Owner], page 252.

off_t st_size

This specifies the size of a regular file in bytes. For files that are really devices and the like, this field isn't usually meaningful.

time_t st_atime

This is the last access time for the file. See Section 13.8.9 [File Times], page 259.

unsigned long int st_atime_usec

This is the fractional part of the last access time for the file. See Section 13.8.9 [File Times], page 259.

time_t st_mtime

This is the time of the last modification to the contents of the file. See Section 13.8.9 [File Times], page 259.

unsigned long int st_mtime_usec

This is the fractional part of the time of last modification to the contents of the file. See Section 13.8.9 [File Times], page 259.

time_t st_ctime

This is the time of the last modification to the attributes of the file. See Section 13.8.9 [File Times], page 259.

unsigned long int st_ctime_usec

This is the fractional part of the time of last modification to the attributes of the file. See Section 13.8.9 [File Times], page 259.

unsigned int st_nblocks

This is the amount of disk space that the file occupies, measured in units of 512-byte blocks.

The number of disk blocks is not strictly proportional to the size of the file, for two reasons: the file system may use some blocks for internal record keeping; and the file may be sparse—it may have "holes" which contain zeros but do not actually take up space on the disk.

You can tell (approximately) whether a file is sparse by comparing this value with st_size, like this:

```
(st.st_blocks * 512 < st.st_size)
```

This test is not perfect because a file that is just slightly sparse might not be detected as sparse at all. For practical applications, this is not a problem.

unsigned int st_blksize

The optimal block size for reading of writing this file. You might use this size for allocating the buffer space for reading of writing the file.

Some of the file attributes have special data type names which exist specifically for those attributes. (They are all aliases for well-known integer types that you know and love.) These typedef names are defined in the header file 'sys/types.h' as well as in 'sys/stat.h'. Here is a list of them.

mode_t Data Type

This is an integer data type used to represent file modes. In the GNU system, this is equivalent to unsigned int.

ino_t Data Type

This is an arithmetic data type used to represent file serial numbers. (In Unix jargon, these are sometimes called *inode numbers*.) In the GNU system, this type is equivalent to unsigned long int.

dev_t Data Type

This is an arithmetic data type used to represent file device numbers. In the GNU system, this is equivalent to int.

nlink_t Data Type

This is an arithmetic data type used to represent file link counts. In the GNU system, this is equivalent to unsigned short int.

13.8.2 Reading the Attributes of a File

To examine the attributes of files, use the functions stat, fstat and lstat. They return the attribute information in a struct stat object. All three functions are declared in the header file 'sys/stat.h'.

int stat (const char *filename, struct stat *buf)

Function

The stat function returns information about the attributes of the file named by filename in the structure pointed at by buf.

If filename is the name of a symbolic link, the attributes you get describe the file that the link points to. If the link points to a nonexistent file name, then stat fails, reporting a nonexistent file.

The return value is 0 if the operation is successful, and -1 on failure. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136, the following error conditions are defined for this function:

ENOENT The file named by filename doesn't exist.

int fstat (int filedes, struct stat *buf)

Function

The fstat function is like stat, except that it takes an open file descriptor as an argument instead of a file name. See Chapter 12 [Low-Level I/O], page 203.

250 The GNU C Library

Like stat, fstat returns 0 on success and -1 on failure. The following errno error conditions are defined for fstat:

EBADF The filedes argument is not a valid file descriptor.

int lstat (const char *filename, struct stat *buf)

Function

The 1stat function is like stat, except that it does not follow symbolic links. If filename is the name of a symbolic link, 1stat returns information about the link itself; otherwise, 1stat works like stat. See Section 13.4 [Symbolic Links], page 240.

13.8.3 Testing the Type of a File

The file mode, stored in the st_mode field of the file attributes, contains two kinds of information: the file type code, and the access permission bits. This section discusses only the type code, which you can use to tell whether the file is a directory, whether it is a socket, and so on. For information about the access permission, Section 13.8.5 [Permission Bits], page 253.

There are two predefined ways you can access the file type portion of the file mode. First of all, for each type of file, there is a *predicate macro* which examines a file mode value and returns true or false—is the file of that type, or not. Secondly, you can mask out the rest of the file mode to get just a file type code. You can compare this against various constants for the supported file types.

All of the symbols listed in this section are defined in the header file 'sys/stat.h'.

The following predicate macros test the type of a file, given the value m which is the st_{mode} field returned by stat on that file:

int S_ISDIR (mode_t m)

Macro

This macro returns nonzero if the file is a directory.

int S_ISCHR (mode_t m)

Macro

This macro returns nonzero if the file is a character special file (a device like a terminal).

int S_ISBLK (mode_t m)

Macro

This macro returns nonzero if the file is a block special file (a device like a disk).

int S_ISREG (mode_t m)

Macro

This macro returns nonzero if the file is a regular file.

int S_ISFIFO (mode_t m)

Macro

This macro returns nonzero if the file is a FIFO special file, or a pipe. See Chapter 14 [Pipes and FIFOs], page 263.

int S_ISLNK (mode_t m)

Macro

This macro returns nonzero if the file is a symbolic link. See Section 13.4 [Symbolic Links], page 240.

int S_ISSOCK (mode_t m)

Macro

This macro returns nonzero if the file is a socket. See Chapter 15 [Sockets], page 269.

An alterate non-POSIX method of testing the file type is supported for compatibility with BSD. The mode can be bitwise ANDed with S_IFMT to extract the file type code, and compared to the appropriate type code constant. For example,

S_ISCHR (mode)

is equivalent to:

 $((mode & S_{IFMT}) == S_{IFCHR})$

int S_IFMT Macro

This is a bit mask used to extract the file type code portion of a mode value.

These are the symbolic names for the different file type codes:

- S_IFDIR This macro represents the value of the file type code for a directory file.
- S_IFCHR This macro represents the value of the file type code for a character-oriented device file.
- S_IFBLK This macro represents the value of the file type code for a block-oriented device file.
- S_IFREG This macro represents the value of the file type code for a regular file.

- S_IFLNK This macro represents the value of the file type code for a symbolic link.
- S_IFSOCK This macro represents the value of the file type code for a socket.
- S_IFIFO This macro represents the value of the file type code for a FIFO or pipe.

13.8.4 File Owner

Every file has an *owner* which is one of the registered user names defined on the system. Each file also has a *group*, which is one of the defined groups. The file owner can often be useful for showing you who edited the file (especially when you edit with GNU Emacs), but its main purpose is for access control.

The file owner and group play a role in determining access because the file has one set of access permission bits for the user that is the owner, another set that apply to users who belong to the file's group, and a third set of bits that apply to everyone else. See Section 13.8.6 [Access Permission], page 255, for the details of how access is decided based on this data.

When a file is created, its owner is set from the effective user ID of the process that creates it (see Section 25.2 [Process Persona], page 521). The file's group ID may be set from either effective group ID of the process, or the group ID of the directory that contains the file, depending on the system where the file is stored. When you access a remote file system, it behaves according to its own rule, not according to the system your program is running on. Thus, your program must be prepared to encounter either kind of behavior, no matter what kind of system you run it on.

You can change the owner and/or group owner of an existing file using the **chown** function. This is the primitive for the **chown** and **chgrp** shell commands.

The prototype for this function is declared in 'unistd.h'.

int chown (const char *filename, uid_t owner, gid_t group) Function

The chown function changes the owner of the file filename to owner, and its group

owner to group.

Changing the owner of the file on certain systems clears the set-user-ID and set-group-ID bits of the file's permissions. (This is because those bits may not be appropriate for the new owner.) The other file permission bits are not changed.

The return value is 0 on success and -1 on failure. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following error conditions are defined for this function:

EPERM This process lacks permission to make the requested change.

Only privileged users or the file's owner can change the file's group. On most file systems, only privileged users can change the file owner; some file systems allow you to change the owner if you are currently the owner. When you access a remote file system, the behavior you encounter is determined by the system that actually holds the file, not by the system your program is running on.

See Section 27.7 [Options for Files], page 555, for information about the _POSIX_CHOWN_RESTRICTED macro.

EROFS The file is on a read-only file system.

int fchown (int filedes, int owner, int group)

Function

This is like **chown**, except that it changes the owner of the file with open file descriptor filedes.

The return value from fchown is 0 on success and -1 on failure. The following errno error codes are defined for this function:

EBADF The filedes argument is not a valid file descriptor.

EINVAL The filedes argument corresponds to a pipe or socket, not an ordinary file.

EPERM This process lacks permission to make the requested change. For details,

see chmod, above.

EROFS The file resides on a read-only file system.

13.8.5 The Mode Bits for Access Permission

The file mode, stored in the st_mode field of the file attributes, contains two kinds of information: the file type code, and the access permission bits. This section discusses only the access permission bits, which control who can read or write the file. See Section 13.8.3 [Testing File Type], page 250, for information about the file type code.

All of the symbols listed in this section are defined in the header file 'sys/stat.h'.

These symbolic constants are defined for the file mode bits that control access permission for the file:

- S_IRUSR
- S_IREAD Read permission bit for the owner of the file. On many systems, this bit is 0400. S_IREAD is an obsolete synonym provided for BSD compatibility.
- S_IWUSR
- S_IWRITE Write permission bit for the owner of the file. Usually 0200. S_IWRITE is an obsolete synonym provided for BSD compatibility.
- S_IXUSR
- S_IEXEC Execute (for ordinary files) or search (for directories) permission bit for the owner of the file. Usually 0100. S_IEXEC is an obsolete synonym provided for BSD compatibility.
- S_IRWXU This is equivalent to '(S_IRUSR | S_IWUSR | S_IXUSR)'.
- S_IRGRP Read permission bit for the group owner of the file. Usually 040.
- S_IWGRP Write permission bit for the group owner of the file. Usually 020.
- S_IXGRP Execute or search permission bit for the group owner of the file. Usually 010.
- S_IRWXG This is equivalent to '(S_IRGRP | S_IWGRP | S_IXGRP)'.
- S_IROTH Read permission bit for other users. Usually 04.
- S_IWOTH Write permission bit for other users. Usually 02.
- S_IXOTH Execute or search permission bit for other users. Usually 01.
- S_IRWXO This is equivalent to '(S_IROTH | S_IWOTH | S_IXOTH)'.
- S_ISUID This is the set-user-ID on execute bit, usually 04000. See Section 25.4 [How Change Persona], page 523.
- S_ISGID This is the set-group-ID on execute bit, usually 02000. See Section 25.4 [How Change Persona], page 523.
- S_ISVTX This is the *sticky* bit, usually 01000.

On an executable file, it modifies the swapping policies of the system. Normally, when a program terminates, its pages in core are immediately freed and reused. If the sticky bit is set on the executable file, the system keeps the pages in core for a while as if the program were still running. This is advantageous for a program that is likely to be run many times in succession.

On a directory, the sticky bit gives permission to delete a file in the directory if you can write the contents of that file. Ordinarily, a user either can delete all the files in the directory or cannot delete any of them (based on whether the user has write permission for the directory). The sticky bit makes it possible to control deletion for individual files.

The actual bit values of the symbols are listed in the table above so you can decode file mode values when debugging your programs. These bit values are correct for most systems, but they are not guaranteed.

Warning: Writing explicit numbers for file permissions is bad practice. It is not only nonportable, it also requires everyone who reads your program to remember what the bits mean. To make your program clean, use the symbolic names.

13.8.6 How Your Access to a File is Decided

Recall that the operating system normally decides access permission for a file based on the effective user and group IDs of the process, and its supplementary group IDs, together with the file's owner, group and permission bits. These concepts are discussed in detail in Section 25.2 [Process Persona], page 521.

If the effective user ID of the process matches the owner user ID of the file, then permissions for read, write, and execute/search are controlled by the corresponding "user" (or "owner") bits. Likewise, if any of the effective group ID or supplementary group IDs of the process matches the group owner ID of the file, then permissions are controlled by the "group" bits. Otherwise, permissions are controlled by the "other" bits.

Privileged users, like 'root', can access any file, regardless of its file permission bits. As a special case, for a file to be executable even for a privileged user, at least one of its execute bits must be set.

13.8.7 Assigning File Permissions

The primitive functions for creating files (for example, open or mkdir) take a mode argument, which specifies the file permissions for the newly created file. But the specified mode is modified by the process's file creation mask, or umask, before it is used.

The bits that are set in the file creation mask identify permissions that are always to be disabled for newly created files. For example, if you set all the "other" access bits in the mask, then newly created files are not accessible at all to processes in the "other" category, even if the *mode* argument specified to the creation function would permit such access. In other words, the file creation mask is the complement of the ordinary access permissions you want to grant.

Programs that create files typically specify a *mode* argument that includes all the permissions that make sense for the particular file. For an ordinary file, this is typically read and write permission for all classes of users. These permissions are then restricted as specified by the individual user's own file creation mask.

To change the permission of an existing file given its name, call chmod. This function ignores the file creation mask; it uses exactly the specified permission bits.

In normal use, the file creation mask is initialized in the user's login shell (using the umask shell command), and inherited by all subprocesses. Application programs normally don't need to worry about the file creation mask. It will do automatically what it is supposed to do.

When your program should create a file and bypass the umask for its access permissions, the easiest way to do this is to use fchmod after opening the file, rather than changing the umask.

In fact, changing the umask is usually done only by shells. They use the umask function.

The functions in this section are declared in 'sys/stat.h'.

mode_t umask (mode_t mask)

Function

The umask function sets the file creation mask of the current process to mask, and returns the previous value of the file creation mask.

Here is an example showing how to read the mask with umask without changing it permanently:

```
mode_t
read_umask (void)
{
  mask = umask (0);
  umask (mask);
}
```

However, it is better to use getumask if you just want to read the mask value, because that is reentrant (at least if you use the GNU operating system).

mode_t getumask (void)

Function

Return the current value of the file creation mask for the current process. This function is a GNU extension.

int chmod (const char *filename, mode_t mode)

Function

The chmod function sets the access permission bits for the file named by filename to mode.

If the *filename* names a symbolic link, chmod changes the permission of the file pointed to by the link, not those of the link itself. There is actually no way to set the mode of a link, which is always -1.

This function returns 0 if successful and -1 if not. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following error conditions are defined for this function:

ENOENT The named file doesn't exist.

EPERM This process does not have permission to change the access permission of this file. Only the file's owner (as judged by the effective user ID of the process) or a privileged user can change them.

EROFS The file resides on a read-only file system.

int fchmod (int filedes, int mode)

Function

This is like chmod, except that it changes the permissions of the file currently open via descriptor filedes.

The return value from fchmod is 0 on success and -1 on failure. The following errno error codes are defined for this function:

EBADF The filedes argument is not a valid file descriptor.

EINVAL The *filedes* argument corresponds to a pipe or socket, or something else that doesn't really have access permissions.

EPERM This process does not have permission to change the access permission of this file. Only the file's owner (as judged by the effective user ID of the process) or a privileged user can change them.

EROFS The file resides on a read-only file system.

13.8.8 Testing Permission to Access a File

When a program runs as a privileged user, this permits it to access files off-limits to ordinary users—for example, to modify '/etc/passwd'. Programs designed to be run by ordinary users but access such files use the setuid bit feature so that they always run with root as the effective user ID.

Such a program may also access files specified by the user, files which conceptually are being accessed explicitly by the user. Since the program runs as root, it has permission to access whatever file the user specifies—but usually the desired behavior is to permit only those files which the user could ordinarily access.

The program therefore must explicitly check whether the user would have the necessary access to a file, before it reads or writes the file.

To do this, use the function access, which checks for access permission based on the process's real user ID rather than the effective user ID. (The setuid feature does not alter the real user ID, so it reflects the user who actually ran the program.)

There is another way you could check this access, which is easy to describe, but very hard to use. This is to examine the file mode bits and mimic the system's own access computation. This method is undesirable because many systems have additional access control features; your program cannot portably mimic them, and you would not want to try to keep track of the diverse features that different systems have. Using access is simple and automatically does whatever is appropriate for the system you are using.

The symbols in this section are declared in 'unistd.h'.

int access (const char *filename, int how)

Function

The access function checks to see whether the file named by filename can be accessed in the way specified by the how argument. The how argument either can be the bitwise OR of the flags R_OK, W_OK, X_OK, or the existence test F_OK.

This function uses the *real* user and group ID's of the calling process, rather than the *effective* ID's, to check for access permission. As a result, if you use the function from a **setuid** or **setgid** program (see Section 25.4 [How Change Persona], page 523), it gives information relative to the user who actually ran the program.

The return value is 0 if the access is permitted, and -1 otherwise. (In other words, treated as a predicate function, access returns true if the requested access is denied.)

In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following error conditions are defined for this function:

EACCES The access specified by how is denied.

ENOENT The file doesn't exist.

EROFS Write permission was requested for a file on a read-only file system.

These macros are defined in the header file 'unistd.h' for use as the how argument to the access function. The values are integer constants.

int R_OK Macro

Argument that means, test for read permission.

int W_OK

Argument that means, test for write permission.

int X_OK

Argument that means, test for execute/search permission.

int F_OK

Argument that means, test for existence of the file.

13.8.9 File Times

Each file has three timestamps associated with it: its access time, its modification time, and its attribute modification time. These correspond to the st_atime, st_mtime, and st_ctime members of the stat structure; see Section 13.8 [File Attributes], page 246.

All of these times are represented in calendar time format, as time_t objects. This data type is defined in 'time.h'. For more information about representation and manipulation of time values, see Section 19.2 [Calendar Time], page 374.

260 The GNU C Library

When an existing file is opened, its attribute change time and modification time fields are updated. Reading from a file updates its access time attribute, and writing updates its modification time.

When a file is created, all three timestamps for that file are set to the current time. In addition, the attribute change time and modification time fields of the directory that contains the new entry are updated.

Adding a new name for a file with the link function updates the attribute change time field of the file being linked, and both the attribute change time and modification time fields of the directory containing the new name. These same fields are affected if a file name is deleted with unlink, remove, or rmdir. Renaming a file with rename affects only the attribute change time and modification time fields of the two parent directories involved, and not the times for the file being renamed.

Changing attributes of a file (for example, with chmod) updates its attribute change time field.

You can also change some of the timestamps of a file explicitly using the utime function—all except the attribute change time. You need to include the header file 'utime.h' to use this facility.

struct utimbuf Data Type

The utimbuf structure is used with the utime function to specify new access and modification times for a file. It contains the following members:

time_t actime

This is the access time for the file.

time_t modtime

This is the modification time for the file.

int utime (const char *filename, const struct utimbuf *times) Function

This function is used to modify the file times associated with the file named filename.

If times is a null pointer, then the access and modification times of the file are set to the current time. Otherwise, they are set to the values from the actime and modtime members (respectively) of the utimbuf structure pointed at by times.

The attribute modification time for the file is set to the current time in either case (since changing the timestamps is itself a modification of the file attributes).

The utime function returns 0 if successful and -1 on failure. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following errno error conditions are defined for this function:

EACCES There is a permission problem in the case where a null pointer was passed as the *times* argument. In order to update the timestamp on the file, you must either be the owner of the file, have write permission on the file, or be a privileged user.

ENOENT The file doesn't exist.

EPERM If the times argument is not a null pointer, you must either be the owner

of the file or be a privileged user. This error is used to report the problem.

EROFS The file lives on a read-only file system.

Each of the three time stamps has a corresponding microsecond part, which extends its resolution. These fields are called st_atime_usec, st_mtime_usec, and st_ctime_usec; each has a value between 0 and 999,999, which indicates the time in microseconds. They correspond to the tv_usec field of a timeval structure; see Section 19.2.2 [High-Resolution Calendar], page 375.

The utimes function is like utime, but also lets you specify the fractional part of the file times. The prototype for this function is in the header file 'sys/time.h'.

int utimes (const char *filename, struct timeval tvp[2])

Function

This function sets the file access and modification times for the file named by *filename*. The new file access time is specified by tvp[0], and the new modification time by tvp[1]. This function comes from BSD.

The return values and error conditions are the same as for the utime function.

13.9 Making Special Files

The mknod function is the primitive for making special files, such as files that correspond to devices. The GNU library includes this function for compatibility with BSD.

The prototype for mknod is declared in 'sys/stat.h'.

int mknod (const char *filename, int mode, int dev)

Function

The mknod function makes a special file with name filename. The mode specifies the mode of the file, and may include the various special file bits, such as S_IFCHR (for a character special file) or S_IFBLK (for a block special file). See Section 13.8.3 [Testing File Type], page 250.

The dev argument specifies which device the special file refers to. Its exact interpretation depends on the kind of special file being created.

The return value is 0 on success and -1 on error. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following error conditions are defined for this function:

EPERM	The calling process is not privileged. Only the superuser can create special files.
ENOSPC	The directory or file system that would contain the new file is "full" and cannot be extended.
EROFS	The directory containing the new file can't be modified because it's on a read-only file system.
EEXIST	There is already a file named <i>filename</i> . If you want to replace this file, you must remove the old file explicitly first.

14 Pipes and FIFOs

A *pipe* is a mechanism for interprocess communication; data written to the pipe by one process can be read by another process. The data is handled in a first-in, first-out (FIFO) order. The pipe has no name; it is created for one use and both ends must be inherited from the single process which created the pipe.

A FIFO special file is similar to a pipe, but instead of being an anonymous, temporary connection, a FIFO has a name or names like any other file. Processes open the FIFO by name in order to communicate through it.

A pipe or FIFO has to be open at both ends simultaneously. If you read from a pipe or FIFO file that doesn't have any processes writing to it (perhaps because they have all closed the file, or exited), the read returns end-of-file. Writing to a pipe or FIFO that doesn't have a reading process is treated as an error condition; it generates a SIGPIPE signal, and fails with error code EPIPE if the signal is handled or blocked.

Neither pipes nor FIFO special files allow file positioning. Both reading and writing operations happen sequentially; reading from the beginning of the file and writing at the end.

14.1 Creating a Pipe

The primitive for creating a pipe is the pipe function. This creates both the reading and writing ends of the pipe. It is not very useful for a single process to use a pipe to talk to itself. In typical use, a process creates a pipe just before it forks one or more child processes (see Section 23.4 [Creating a Process], page 483). The pipe is then used for communication either between the parent or child processes, or between two sibling processes.

The pipe function is declared in the header file 'unistd.h'.

int pipe (int filedes[2])

Function

The pipe function creates a pipe and puts the file descriptors for the reading and writing ends of the pipe (respectively) into filedes [0] and filedes [1].

An easy way to remember that the input end comes first is that file descriptor 0 is standard input, and file descriptor 1 is standard output.

If successful, pipe returns a value of 0. On failure, -1 is returned. The following errno error conditions are defined for this function:

EMFILE The process has too many files open.

ENFILE There are too many open files in the entire system. See Section 2.2 [Error Codes], page 17, for more information about ENFILE.

Here is an example of a simple program that creates a pipe. This program uses the **fork** function (see Section 23.4 [Creating a Process], page 483) to create a child process. The parent process writes data to the pipe, which is read by the child process.

```
#include <sys/types.h>
#include <unistd.h>
#include <stdio.h>
#include <stdlib.h>
/* Read characters from the pipe and echo them to stdout. */
void
read_from_pipe (int file)
  FILE *stream;
  int c;
  stream = fdopen (file, "r");
  while ((c = fgetc (stream)) != EOF)
    putchar (c);
 fclose (stream);
/* Write some random text to the pipe. */
void
write_to_pipe (int file)
  FILE *stream;
  stream = fdopen (file, "w");
  fprintf (stream, "hello, world!\n");
  fprintf (stream, "goodbye, world!\n");
  fclose (stream);
}
int
main (void)
```

```
pid_t pid;
  int mypipe[2];
  /* Create the pipe. */
  if (pipe (mypipe))
    {
      fprintf (stderr, "Pipe failed.\n");
      return EXIT_FAILURE;
    }
  /* Create the child process. */
 pid = fork ();
  if (pid == (pid_t) 0)
      /* This is the child process. */
      read_from_pipe (mypipe[0]);
      return EXIT_SUCCESS;
    }
  else if (pid < (pid_t) 0)
    {
      /* The fork failed. */
      fprintf (stderr, "Fork failed.\n");
      return EXIT_FAILURE;
    }
  else
      /* This is the parent process. */
      write_to_pipe (mypipe[1]);
      return EXIT_SUCCESS;
}
```

14.2 Pipe to a Subprocess

A common use of pipes is to send data to or receive data from a program being run as subprocess. One way of doing this is by using a combination of pipe (to create the pipe), fork (to create the subprocess), dup2 (to force the subprocess to use the pipe as its standard input or output channel), and exec (to execute the new program). Or, you can use popen and pclose.

The advantage of using popen and pclose is that the interface is much simpler and easier to use. But it doesn't offer as much flexibility as using the low-level functions directly.

FILE * popen (const char *command, const char *mode)

Function

The popen function is closely related to the system function; see Section 23.1 [Running a Command], page 481. It executes the shell command command as a subprocess. However, instead of waiting for the command to complete, it creates a pipe to the subprocess and returns a stream that corresponds to that pipe.

If you specify a *mode* argument of "r", you can read from the stream to retrieve data from the standard output channel of the subprocess. The subprocess inherits its standard input channel from the parent process.

Similarly, if you specify a *mode* argument of "w", you can write to the stream to send data to the standard input channel of the subprocess. The subprocess inherits its standard output channel from the parent process.

In the event of an error, popen returns a null pointer. This might happen if the pipe or stream cannot be created, if the subprocess cannot be forked, or if the program cannot be executed.

int pclose (FILE *stream)

Function

The pclose function is used to close a stream created by popen. It waits for the child process to terminate and returns its status value, as for the system function.

Here is an example showing how to use popen and pclose to filter output through another program, in this case the paging program more.

```
#include <stdio.h>
#include <stdib.h>

void
write_data (FILE * stream)
{
   int i;
   for (i = 0; i < 100; i++)
      fprintf (stream, "%d\n", i);
   if (ferror (stream))
      {
      fprintf (stderr, "Output to stream failed.\n");
      exit (EXIT_FAILURE);
   }
}</pre>
```

```
int
main (void)
{
   FILE *output;
   output = popen ("more", "w");
   if (!output)
      {
        fprintf (stderr, "Could not run more.\n");
        return EXIT_FAILURE;
      }
   write_data (output);
   pclose (output);
   return EXIT_SUCCESS;
}
```

14.3 FIFO Special Files

A FIFO special file is similar to a pipe, except that it is created in a different way. Instead of being an anonymous communications channel, a FIFO special file is entered into the file system by calling mkfifo.

Once you have created a FIFO special file in this way, any process can open it for reading or writing, in the same way as an ordinary file. However, it has to be open at both ends simultaneously before you can proceed to do any input or output operations on it. Opening a FIFO for reading normally blocks until some other process opens the same FIFO for writing, and vice versa.

The mkfifo function is declared in the header file 'sys/stat.h'.

```
int mkfifo (const char *filename, mode_t mode)
```

Function

The mkfifo function makes a FIFO special file with name filename. The mode argument is used to set the file's permissions; see Section 13.8.7 [Setting Permissions], page 255.

The normal, successful return value from mkfifo is 0. In the case of an error, -1 is returned. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following error conditions are defined for this function:

268 The GNU C Library

EEXIST The named file already exists.

ENOSPC The directory or file system cannot be extended.

EROFS The directory that would contain the file resides on a read-only file system.

14.4 Atomicity of Pipe I/O

Reading or writing pipe data is *atomic* if the size of data written is less than PIPE_BUF. This means that the data transfer seems to be an instantaneous unit, in that nothing else in the system can observe a state in which it is partially complete. Atomic I/O may not begin right away (it may need to wait for buffer space or for data), but once it does begin, it finishes immediately.

Reading or writing a larger amount of data may not be atomic; for example, output data from other processes sharing the descriptor may be interspersed.

See Section 27.6 [Limits for Files], page 553, for information about the PIPE_BUF parameter.

15 Sockets

This chapter describes the GNU facilities for interprocess communication using sockets.

A socket is a generalized interprocess communication channel. Like a pipe, a socket is represented as a file descriptor. But, unlike pipes, sockets support communication between unrelated processes, and even between processes running on different machines that communicate over a network. Sockets are the primary means of communicating with other machines; telnet, rlogin, ftp, talk, and the other familiar network programs use sockets.

Not all operating systems support sockets. In the GNU library, the header file 'sys/socket.h' exists regardless of the operating system, and the socket functions always exist, but if the system does not really support sockets, these functions always fail.

Incomplete: We do not currently document the facilities for broadcast messages or for configuring Internet interfaces.

15.1 Socket Concepts

When you create a socket, you must specify the style of communication you want to use and the type of protocol that should implement it. The *communication style* of a socket defines the user-level semantics of sending and receiving data on the socket. Choosing a communication style specifies the answers to questions such as these:

- What are the units of data transmission? Some communication styles regard the data as a sequence of bytes, with no larger structure; others group the bytes into records (which are known in this context as packets).
- Can data be lost during normal operation? Some communication styles guarantee that all the data sent arrives in the order it was sent (barring system or network crashes); others styles occasionally lose data as a normal part of operation, and may sometimes deliver packets more than once or in the wrong order.
 - Designing a program to use unreliable communication styles usually involves taking precautions to detect lost or misordered packets and to retransmit data as needed.
- Is communication entirely with one partner? Some communication styles are like a telephone call—you make a *connection* with one remote socket, and then exchange data freely. Other styles are like mailing letters—you specify a destination address for each message you send.

You must also choose a namespace for naming the socket. A socket name ("address") is meaningful only in the context of a particular namespace. In fact, even the data type to use for a socket name may depend on the namespace. Namespaces are also called "domains", but we avoid that word as it can be confused with other usage of the same term. Each namespace has a symbolic name that starts with 'PF_'. A corresponding symbolic name starting with 'AF_' designates the address format for that namespace.

Finally you must next choose the *protocol* to carry out the communication. The protocol determines what low-level mechanism is used to transmit and receive data. Each protocol is valid for a particular namespace and communication style; a namespace is sometimes called a *protocol* family because of this, which is why the namespace names start with 'PF_'.

The rules of a protocol apply to the data passing between two programs, perhaps on different computers; most of these rules are handled by the operating system, and you need not know about them. What you do need to know about protocols is this:

- In order to have communication between two sockets, they must specify the same protocol.
- Each protocol is meaningful with particular style/namespace combinations and cannot be used with inappropriate combinations. For example, the TCP protocol fits only the byte stream style of communication and the Internet namespace.
- For each combination of style and namespace, there is a default protocol which you can request by specifying 0 as the protocol number. And that's what you should normally do—use the default.

15.2 Communication Styles

The GNU library includes support for several different kinds of sockets, each with different characteristics. This section describes the supported socket types. The symbolic constants listed here are defined in 'sys/socket.h'.

int SOCK_STREAM

Macro

The SOCK_STREAM style is like a pipe (see Chapter 14 [Pipes and FIFOs], page 263); it operates over a connection with a particular remote socket, and transmits data reliably as a stream of bytes.

Use of this style is covered in detail in Section 15.8 [Connections], page 295.

int SOCK_DGRAM

Macro

The SOCK_DGRAM style is used for sending individually-addressed packets, unreliably. It is the diametrical opposite of SOCK_STREAM.

Each time you write data to a socket of this kind, that data becomes one packet. Since SOCK_DGRAM sockets do not have connections, you must specify the recipient address with each packet.

The only guarantee that the system makes about your requests to transmit data is that it will try its best to deliver each packet you send. It may succeed with the sixth packet after failing with the fourth and fifth packets; the seventh packet may arrive before the sixth, and may arrive a second time after the sixth.

The typical use for SOCK_DGRAM is in situations where it is acceptible to simply resend a packet if no response is seen in a reasonable amount of time.

See Section 15.9 [Datagrams], page 309, for detailed information about how to use datagram sockets.

int SOCK_RAW Macro

This style provides access to low-level network protocols and interfaces. Ordinary user programs usually have no need to use this style.

15.3 Socket Addresses

The name of a socket is normally called an address. The functions and symbols for dealing with socket addresses were named inconsistently, sometimes using the term "name" and sometimes using "address". You can regard these terms as synonymous where sockets are concerned.

A socket newly created with the socket function has no address. Other processes can find it for communication only if you give it an address. We call this *binding* the address to the socket, and the way to do it is with the bind function.

You need be concerned with the address of a socket if other processes are to find it and start communicating with it. You can specify an address for other sockets, but this is usually pointless; the first time you send data from a socket, or use it to initiate a connection, the system assigns an address automatically if you have not specified one.

272 The GNU C Library

Occasionally a client needs to specify an address because the server discriminates based on addresses; for example, the rsh and rlogin protocols look at the client's socket address and don't bypass password checking unless it is less than IPPORT_RESERVED (see Section 15.5.3 [Ports], page 285).

The details of socket addresses vary depending on what namespace you are using. See Section 15.4 [File Namespace], page 275, or Section 15.5 [Internet Namespace], page 278, for specific information.

Regardless of the namespace, you use the same functions bind and getsockname to set and examine a socket's address. These functions use a phony data type, struct sockaddr *, to accept the address. In practice, the address lives in a structure of some other data type appropriate to the address format you are using, but you cast its address to struct sockaddr * when you pass it to bind.

15.3.1 Address Formats

The functions bind and getsockname use the generic data type struct sockaddr * to represent a pointer to a socket address. You can't use this data type effectively to interpret an address or construct one; for that, you must use the proper data type for the socket's namespace.

Thus, the usual practice is to construct an address in the proper namespace-specific type, then cast a pointer to struct sockaddr * when you call bind or getsockname.

The one piece of information that you can get from the struct sockaddr data type is the address format designator which tells you which data type to use to understand the address fully.

The symbols in this section are defined in the header file 'sys/socket.h'.

struct sockaddr Date Type

The struct sockaddr type itself has the following members:

short int sa_family

This is the code for the address format of this address. It identifies the format of the data which follows.

char sa_data[14]

This is the actual socket address data, which is format-dependent. Its length is also format-dependent, and may well be more than 14. The length 14 of sa_data is essentially arbitrary.

Each address format has a symbolic name which starts with 'AF_'. Each of them corresponds to a 'PF_' symbol which designates the corresponding namespace. Here is a list of address format names:

- AF_FILE This designates the address format that goes with the file namespace. (PF_FILE is the name of that namespace.) See Section 15.4.2 [File Namespace Details], page 276, for information about this address format.
- AF_UNIX This is a synonym for AF_FILE, for compatibility. (PF_UNIX is likewise a synonym for PF_FILE.)
- AF_INET This designates the address format that goes with the Internet namespace. (PF_INET is the name of that namespace.) See Section 15.5.1 [Internet Address Format], page 279.

AF_UNSPEC

This designates no particular address format. It is used only in rare cases, such as to clear out the default destination address of a "connected" datagram socket. See Section 15.9.1 [Sending Datagrams], page 309.

The corresponding namespace designator symbol PF_UNSPEC exists for completeness, but there is no reason to use it in a program.

'sys/socket.h' defines symbols starting with 'AF_' for many different kinds of networks, all or most of which are not actually implemented. We will document those that really work, as we receive information about how to use them.

15.3.2 Setting a Socket's Address

Use the bind function to assign an address to a socket. The prototype for bind is in the header file 'sys/socket.h'. For examples of use, see Section 15.4 [File Namespace], page 275, or see Section 15.5.7 [Inet Example], page 290.

int bind (int socket, struct sockaddr *addr, size_t length)

Function

The bind function assigns an address to the socket socket. The addr and length arguments specify the address; the detailed format of the address depends on the namespace. The first part of the address is always the format designator, which specifies a namespace, and says that the address is in the format for that namespace.

The return value is 0 on success and -1 on failure. The following errno error conditions are defined for this function:

EBADF The socket argument is not a valid file descriptor.

ENOTSOCK The descriptor socket is not a socket.

EADDRNOTAVAIL

The specified address is not available on this machine.

EADDRINUSE

Some other socket is already using the specified address.

EINVAL The socket socket already has an address.

EACCESS You do not have permission to access the requested address. (In the Inter-

net domain, only the super-user is allowed to specify a port number in the range 0 through IPPORT_RESERVED minus one; see Section 15.5.3 [Ports],

page 285.)

Additional conditions may be possible depending on the particular namespace of the socket.

15.3.3 Reading a Socket's Address

Use the function getsockname to examine the address of an Internet socket. The prototype for this function is in the header file 'sys/socket.h'.

The getsockname function returns information about the address of the socket socket in the locations specified by the addr and length_ptr arguments. Note that the length_ptr is a pointer; you should initialize it to be the allocation size of addr, and on return it contains the actual size of the address data.

The format of the address data depends on the socket namespace. The length of the information is usually fixed for a given namespace, so normally you can know exactly how much space is needed and can provide that much. The usual practice is to allocate a place for the value using the proper data type for the socket's namespace, then cast its address to struct sockaddr * to pass it to getsockname.

The return value is 0 on success and -1 on error. The following errno error conditions are defined for this function:

EBADF The socket argument is not a valid file descriptor.

ENOTSOCK The descriptor socket is not a socket.

ENOBUFS There are not enough internal buffers available for the operation.

You can't read the address of a socket in the file namespace. This is consistent with the rest of the system; in general, there's no way to find a file's name from a descriptor for that file.

15.4 The File Namespace

This section describes the details of the file namespace, whose symbolic name (required when you create a socket) is PF_FILE.

15.4.1 File Namespace Concepts

In the file namespace, socket addresses are file names. You can specify any file name you want as the address of the socket, but you must have write permission on the directory containing it. In order to connect to a socket, you must have read permission for it. It's common to put these files in the '/tmp' directory.

One peculiarity of the file namespace is that the name is only used when opening the connection; once that is over with, the address is not meaningful and may not exist.

Another peculiarity is that you cannot connect to such a socket from another machine—not even if the other machine shares the file system which contains the name of the socket. You can see the socket in a directory listing, but connecting to it never succeeds. Some programs take advantage of this, such as by asking the client to send its own process ID, and using the process IDs to distinguish

276 The GNU C Library

between clients. However, we recommend you not use this method in protocols you design, as we might someday permit connections from other machines that mount the same file systems. Instead, send each new client an identifying number if you want it to have one.

After you close a socket in the file namespace, you should delete the file name from the file system. Use unlink or remove to do this; see Section 13.5 [Deleting Files], page 242.

The file namespace supports just one protocol for any communication style; it is protocol number 0.

15.4.2 Details of File Namespace

To create a socket in the file namespace, use the constant PF_FILE as the namespace argument to socket or socketpair. This constant is defined in 'sys/socket.h'.

int PF_FILE Macro

This designates the file namespace, in which socket addresses are file names, and its associated family of protocols.

int PF_UNIX Macro

This is a synonym for PF_FILE, for compatibility's sake.

The structure for specifying socket names in the file namespace is defined in the header file 'sys/un.h':

struct sockaddr_un Data Type

This structure is used to specify file namespace socket addresses. It has the following members:

short int sun_family

This identifies the address family or format of the socket address. You should store the value AF_FILE to designate the file namespace. See Section 15.3 [Socket Addresses], page 271.

char sun_path[108]

This is the file name to use.

Incomplete: Why is 108 a magic number? RMS suggests making this a zero-length array and tweaking the example following to use alloca to allocate an appropriate amount of storage based on the length of the filename.

You should compute the *length* parameter for a socket address in the file namespace as the sum of the size of the sun_family component and the string length (*not* the allocation size!) of the file name string.

15.4.3 Example of File-Namespace Sockets

Here is an example showing how to create and name a socket in the file namespace.

```
#include <stddef.h>
#include <stdio.h>
#include <errno.h>
#include <stdlib.h>
#include <sys/socket.h>
#include <sys/un.h>
int
make_named_socket (const char *filename)
  struct sockaddr_un name;
  int sock;
  size_t size;
  /* Create the socket. */
  sock = socket (PF_UNIX, SOCK_DGRAM, 0);
  if (sock < 0)
      perror ("socket");
      exit (EXIT_FAILURE);
  /* Bind a name to the socket. */
 name.sun_family = AF_FILE;
  strcpy (name.sun_path, filename);
```

```
/* The size of the address is
    the offset of the start of the filename,
    plus its length,
    plus one for the terminating null byte. */
size = (offsetof (struct sockaddr_un, sun_path)
+ strlen (name.sun_path) + 1);

if (bind (sock, (struct sockaddr *) &name, size) < 0)
    {
        perror ("bind");
        exit (EXIT_FAILURE);
    }

return sock;
}</pre>
```

15.5 The Internet Namespace

This section describes the details the protocols and socket naming conventions used in the Internet namespace.

To create a socket in the Internet namespace, use the symbolic name PF_INET of this namespace as the namespace argument to socket or socketpair. This macro is defined in 'sys/socket.h'.

int PF_INET Macro

This designates the Internet namespace and associated family of protocols.

A socket address for the Internet namespace includes the following components:

- The address of the machine you want to connect to. Internet addresses can be specified in several ways; these are discussed in Section 15.5.1 [Internet Address Format], page 279, Section 15.5.2 [Host Addresses], page 279, and Section 15.5.2.4 [Host Names], page 282.
- A port number for that machine. See Section 15.5.3 [Ports], page 285.

You must ensure that the address and port number are represented in a canonical format called network byte order. See Section 15.5.5 [Byte Order], page 287, for information about this.

15.5.1 Internet Socket Address Format

In the Internet namespace, a socket address consists of a host address and a port on that host. In addition, the protocol you choose serves effectively as a part of the address because local port numbers are meaningful only within a particular protocol.

The data type for representing socket addresses in the Internet namespace is defined in the header file 'netinet/in.h'.

struct sockaddr_in Data Type

This is the data type used to represent socket addresses in the Internet namespace. It has the following members:

short int sin_family

This identifies the address family or format of the socket address. You should store the value of AF_INET in this member. See Section 15.3 [Socket Addresses], page 271.

struct in_addr sin_addr

This is the Internet address of the host machine. See Section 15.5.2 [Host Addresses], page 279, and Section 15.5.2.4 [Host Names], page 282, for how to get a value to store here.

unsigned short int sin_port

This is the port number. See Section 15.5.3 [Ports], page 285.

When you call bind or getsockname, you should specify sizeof (struct sockaddr_in) as the length parameter if you are using an Internet namespace socket address.

15.5.2 Host Addresses

Each computer on the Internet has one or more *Internet addresses*, numbers which identify that computer among all those on the Internet. Users typically write numeric host addresses as sequences of four numbers, separated by periods, as in '128.52.46.32'.

Each computer also has one or more *host names*, which are strings of words separated by periods, as in 'churchy.gnu.ai.mit.edu'.

280 The GNU C Library

Programs that let the user specify a host typically accept both numeric addresses and host names. But the program needs a numeric address to open a connection; to use a host name, you must convert it to the numeric address it stands for.

15.5.2.1 Internet Host Addresses

An Internet host address is a number containing four bytes of data. These are divided into two parts, a network number and a local network address number within that network. The network number consists of the first one, two or three bytes; the rest of the bytes are the local address.

Network numbers are registered with the Network Information Center (NIC), and are divided into three classes—A, B, and C. The local network address numbers of individual machines are registered with the administrator of the particular network.

Class A networks have single-byte numbers in the range 0 to 127. There are only a small number of Class A networks, but they can each support a very large number of hosts. Medium-sized Class B networks have two-byte network numbers, with the first byte in the range 128 to 191. Class C networks are the smallest; they have three-byte network numbers, with the first byte in the range 192-255. Thus, the first 1, 2, or 3 bytes of an Internet address specifies a network. The remaining bytes of the Internet address specify the address within that network.

The Class A network 0 is reserved for broadcast to all networks. In addition, the host number 0 within each network is reserved for broadcast to all hosts in that network.

The Class A network 127 is reserved for loopback; you can always use the Internet address '127.0.0.1' to refer to the host machine.

Since a single machine can be a member of multiple networks, it can have multiple Internet host addresses. However, there is never supposed to be more than one machine with the same host address.

There are four forms of the standard numbers-and-dots notation for Internet addresses:

- a.b.c.d This specifies all four bytes of the address individually.
- a.b.c The last part of the address, c, is interpreted as a 2-byte quantity. This is useful for specifying host addresses in a Class B network with network address number a.b.
- a.b The last part of the address, c, is interpreted as a 3-byte quantity. This is useful for specifying host addresses in a Class A network with network address number a.

a If only one part is given, this corresponds directly to the host address number.

Within each part of the address, the usual C conventions for specifying the radix apply. In other words, a leading '0x' or '0X' implies hexadecimal radix; a leading '0' implies octal; and otherwise decimal radix is assumed.

15.5.2.2 Host Address Data Type

Internet host addresses are represented in some contexts as integers (type unsigned long int). In other contexts, the integer is packaged inside a structure of type struct in_addr. It would be better if the usage were made consistent, but it is not hard to extract the integer from the structure or put the integer into a structure.

The following basic definitions for Internet addresses appear in the header file 'netinet/in.h':

struct in_addr Data Type

This data type is used in certain contexts to contain an Internet host address. It has just one field, named s_addr, which records the host address number as an unsigned long int.

unsigned long int INADDR_ANY

Macro

You can use this constant to stand for "the address of this machine," instead of finding its actual address. This special constant saves you the trouble of looking up the address of your own machine. Also, if your machine has multiple network addresses on different networks (which is not unusual), using INADDR_ANY permits the system to choose whichever address makes communication most efficient.

15.5.2.3 Host Address Functions

These additional functions for manipulating Internet addresses are declared in 'arpa/inet.h'. They represent Internet addresses in network byte order; they represent network numbers and local-address-within-network numbers in host byte order. See Section 15.5.5 [Byte Order], page 287, for an explanation of network and host byte order.

unsigned long int inet_addr (const char *name)

Function

This function converts the Internet host address name from the standard numbers-and-dots notation into binary data. If the input is not valid, inet_addr returns -1.

unsigned long int inet_network (const char *name)

Function

This function extracts the network number from the address name, given in the standard numbers-and-dots notation. If the input is not valid, inet_network returns -1.

char * inet_ntoa (struct in_addr addr)

Function

This function converts the Internet host address addr to a string in the standard numbers-and-dots notation. The return value is a pointer into a statically-allocated buffer. Subsequent calls will overwrite the same buffer, so you should copy the string if you need to save it.

struct in_addr inet_makeaddr (int net, int local)

Function

This function makes an Internet host address by combining the network number *net* with the local-address-within-network number *local*.

int inet_lnaof (struct in_addr addr)

Function

This function returns the local-address-within-network part of the Internet host address addr.

int inet_netof (struct in_addr addr)

Function

This function returns the network number part of the Internet host address addr.

15.5.2.4 Host Names

Besides the standard numbers-and-dots notation for Internet addresses, you can also refer to a host by a symbolic name. The advantage of a symbolic name is that it is usually easier to remember. For example, the machine with Internet address '128.52.46.32' is also known as 'churchy.gnu.ai.mit.edu'; and other machines in the 'gnu.ai.mit.edu' domain can refer to it simply as 'churchy'.

Internally, the system uses a database to keep track of the mapping between host names and host numbers. This database is usually either the file '/etc/hosts' or an equivalent provided by a name server. The functions and other symbols for accessing this database are declared in 'netdb.h'. They are BSD features, defined unconditionally if you include 'netdb.h'.

struct hostent Data Type

This data type is used to represent an entry in the hosts database. It has the following members:

char *h_name

This is the "official" name of the host.

char **h_aliases

These are alternative names for the host, represented as a null-terminated vector of strings.

int h_addrtype

This is the host address type; in practice, its value is always AF_INET. In principle other kinds of addresses could be represented in the data base as well as Internet addresses; if this were done, you might find a value in this field other than AF_INET. See Section 15.3 [Socket Addresses], page 271.

int h_length

This is the length, in bytes, of each address.

char **h_addr_list

This is the vector of addresses for the host. (Recall that the host might be connected to multiple networks and have different addresses on each one.) The vector is terminated by a null pointer.

char *h_addr

This is a synonym for h_addr_list[0]; in other words, it is the first host address.

As far as the host database is concerned, each address is just a block of memory h_length bytes long. But in other contexts there is an implicit assumption that you can convert this to a struct in_addr or an unsigned long int. Host addresses in a struct hostent structure are always given in network byte order; see Section 15.5.5 [Byte Order], page 287.

You can use gethostbyname or gethostbyaddr to search the hosts database for information about a particular host. The information is returned in a statically-allocated structure; you must copy the information if you need to save it across calls.

struct hostent * gethostbyname (const char *name)

Function

The gethostbyname function returns information about the host named name. If the lookup fails, it returns a null pointer.

284 The GNU C Library

The gethostbyaddr function returns information about the host with Internet address addr. The length argument is the size (in bytes) of the address at addr. format specifies the address format; for an Internet address, specify a value of AF_INET.

If the lookup fails, gethostbyaddr returns a null pointer.

If the name lookup by gethostbyname or gethostbyaddr fails, you can find out the reason by looking at the value of the variable h_errno. (It would be cleaner design for these functions to set errno, but use of h_errno is compatible with other systems.) Before using h_errno, you must declare it like this:

extern int h_errno;

Here are the error codes that you may find in h_errno:

HOST_NOT_FOUND

No such host is known in the data base.

TRY_AGAIN

This condition happens when the name server could not be contacted. If you try again later, you may succeed then.

NO_RECOVERY

A non-recoverable error occurred.

NO_ADDRESS

The host database contains an entry for the name, but it doesn't have an associated Internet address.

You can also scan the entire hosts database one entry at a time using sethostent, gethostent, and endhostent. Be careful in using these functions, because they are not reentrant.

void sethostent (int stayopen)

Function

This function opens the hosts database to begin scanning it. You can then call gethostent to read the entries.

If the stayopen argument is nonzero, this sets a flag so that subsequent calls to gethostbyname or gethostbyaddr will not close the database (as they usually would). This makes for more efficiency if you call those functions several times, by avoiding reopening the database for each call.

struct hostent * gethostent ()

Function

This function returns the next entry in the hosts database. It returns a null pointer if there are no more entries.

void endhostent ()

Function

This function closes the hosts database.

15.5.3 Internet Ports

A socket address in the Internet namespace consists of a machine's Internet address plus a *port* number which distinguishes the sockets on a given machine (for a given protocol). Port numbers range from 0 to 65,535.

Port numbers less than IPPORT_RESERVED are reserved for standard servers, such as finger and telnet. There is a database that keeps track of these, and you can use the getservbyname function to map a service name onto a port number; see Section 15.5.4 [Services Database], page 286.

If you write a server that is not one of the standard ones defined in the database, you must choose a port number for it. Use a number greater than IPPORT_USERRESERVED; such numbers are reserved for servers and won't ever be generated automatically by the system. Avoiding conflicts with servers being run by other users is up to you.

When you use a socket without specifying its address, the system generates a port number for it. This number is between IPPORT_RESERVED and IPPORT_USERRESERVED.

On the Internet, it is actually legitimate to have two different sockets with the same port number, as long as they never both try to communicate with the same socket address (host address plus port number). You shouldn't duplicate a port number except in special circumstances where a higher-level protocol requires it. Normally, the system won't let you do it; bind normally insists on distinct port numbers. To reuse a port number, you must set the socket option SO_REUSEADDR. See Section 15.11.2 [Socket-Level Options], page 317.

These macros are defined in the header file 'netinet/in.h'.

int IPPORT_RESERVED

Macro

Port numbers less than IPPORT_RESERVED are reserved for superuser use.

int IPPORT_USERRESERVED

Macro

Port numbers greater than or equal to IPPORT_USERRESERVED are reserved for explicit use; they will never be allocated automatically.

15.5.4 The Services Database

The database that keeps track of "well-known" services is usually either the file '/etc/services' or an equivalent from a name server. You can use these utilities, declared in 'netdb.h', to access the services database.

struct servent Data Type

This data type holds information about entries from the services database. It has the following members:

char *s_name

This is the "official" name of the service.

char **s_aliases

These are alternate names for the service, represented as an array of strings. A null pointer terminates the array.

int s_port

This is the port number for the service. Port numbers are given in network byte order; see Section 15.5.5 [Byte Order], page 287.

char *s_proto

This is the name of the protocol to use with this service. See Section 15.5.6 [Protocols Database], page 289.

To get information about a particular service, use the getservbyname or getservbyport functions. The information is returned in a statically-allocated structure; you must copy the information if you need to save it across calls.

struct servent * getservbyname (const char *name, const char *proto)

Function

The getservbyname function returns information about the service named name using protocol proto. If it can't find such a service, it returns a null pointer.

This function is useful for servers as well as for clients; servers use it to determine which port they should listen on (see Section 15.8.2 [Listening], page 296).

struct servent * getservbyport (int port, const char *proto)

Function

The getservbyport function returns information about the service at port port using protocol proto. If it can't find such a service, it returns a null pointer.

You can also scan the services database using setservent, getservent, and endservent. Be careful in using these functions, because they are not reentrant.

void setservent (int stayopen)

Function

This function opens the services database to begin scanning it.

If the *stayopen* argument is nonzero, this sets a flag so that subsequent calls to **getservbyname** or **getservbyport** will not close the database (as they usually would). This makes for more efficiency if you call those functions several times, by avoiding reopening the database for each call.

struct servent * getservent (void)

Function

This function returns the next entry in the services database. If there are no more entries, it returns a null pointer.

void endservent (void)

Function

This function closes the services database.

15.5.5 Byte Order Conversion

Different kinds of computers use different conventions for the ordering of bytes within a word. Some computers put the most significant byte within a word first (this is called "big-endian" order), and others put it last ("little-endian" order).

The GNU C Library

So that machines with different byte order conventions can communicate, the Internet protocols specify a canonical byte order convention for data transmitted over the network. This is known as the *network byte order*.

When establishing an Internet socket connection, you must make sure that the data in the sin_port and sin_addr members of the sockaddr_in structure are represented in the network byte order. If you are encoding integer data in the messages sent through the socket, you should convert this to network byte order too. If you don't do this, your program may fail when running on or talking to other kinds of machines.

If you use getservbyname and gethostbyname or inet_addr to get the port number and host address, the values are already in the network byte order, and you can copy them directly into the sockaddr_in structure.

Otherwise, you have to convert the values explicitly. Use htons and ntohs to convert values for the sin_port member. Use hton1 and ntoh1 to convert values for the sin_addr member. (Remember, struct in_addr is equivalent to unsigned long int.) These functions are declared in 'netinet/in.h'.

unsigned short int htons (unsigned short int hostshort)

288

Function

This function converts the **short** integer *hostshort* from host byte order to network byte order.

unsigned short int ntohs (unsigned short int netshort)

Function

This function converts the **short** integer *netshort* from network byte order to host byte order.

unsigned long int htonl (unsigned long int hostlong)

Function

This function converts the long integer hostlong from host byte order to network byte order.

unsigned long int ntohl (unsigned long int netlong)

Function

This function converts the long integer netlong from network byte order to host byte order.

15.5.6 Protocols Database

The communications protocol used with a socket controls low-level details of how data is exchanged. For example, the protocol implements things like checksums to detect errors in transmissions, and routing instructions for messages. Normal user programs have little reason to mess with these details directly.

The default communications protocol for the Internet namespace depends on the communication style. For stream communication, the default is TCP ("transmission control protocol"). For datagram communication, the default is UDP ("user datagram protocol"). For reliable datagram communication, the default is RDP ("reliable datagram protocol"). You should nearly always use the default.

Internet protocols are generally specified by a name instead of a number. The network protocols that a host knows about are stored in a database. This is usually either derived from the file '/etc/protocols', or it may be an equivalent provided by a name server. You look up the protocol number associated with a named protocol in the database using the getprotobyname function.

Here are detailed descriptions of the utilities for accessing the protocols database. These are declared in 'netdb.h'.

struct protoent Data Type

This data type is used to represent entries in the network protocols database. It has the following members:

char *p_name

This is the official name of the protocol.

char **p_aliases

These are alternate names for the protocol, specified as an array of strings. The last element of the array is a null pointer.

int p_proto

This is the protocol number (in host byte order); use this member as the protocol argument to socket.

You can use getprotobyname and getprotobynumber to search the protocols database for a specific protocol. The information is returned in a statically-allocated structure; you must copy the information if you need to save it across calls.

struct protoent * getprotobyname (const char *name)

Function

The getprotobyname function returns information about the network protocol named name. If there is no such protocol, it returns a null pointer.

struct protoent * getprotobynumber (int protocol)

Function

The getprotobynumber function returns information about the network protocol with number protocol. If there is no such protocol, it returns a null pointer.

You can also scan the whole protocols database one protocol at a time by using setprotoent, getprotoent, and endprotoent. Be careful in using these functions, because they are not reentrant.

void setprotoent (int stayopen)

Function

This function opens the protocols database to begin scanning it.

If the *stayopen* argument is nonzero, this sets a flag so that subsequent calls to **getprotobyname** or **getprotobynumber** will not close the database (as they usually would). This makes for more efficiency if you call those functions several times, by avoiding reopening the database for each call.

struct protoent * getprotoent (void)

Function

This function returns the next entry in the protocols database. It returns a null pointer if there are no more entries.

void endprotoent (void)

Function

This function closes the protocols database.

15.5.7 Internet Socket Example

Here is an example showing how to create and name a socket in the Internet namespace. The newly created socket exists on the machine that the program is running on. Rather than finding and using the machine's Internet address, this example specifies INADDR_ANY as the host address; the system replaces that with the machine's actual address.

```
#include <stdio.h>
#include <stdlib.h>
#include <sys/socket.h>
```

```
#include <netinet/in.h>
make_socket (unsigned short int port)
  int sock;
  struct sockaddr_in name;
  /* Create the socket. */
  sock = socket (PF_INET, SOCK_STREAM, 0);
  if (sock < 0)
    {
     perror ("socket");
      exit (EXIT_FAILURE);
  /* Give the socket a name. */
 name.sin_family = AF_INET;
 name.sin_port = htons (port);
  name.sin_addr.s_addr = htonl (INADDR_ANY);
  if (bind (sock, (struct sockaddr *) &name, sizeof (name)) < 0)
     perror ("bind");
      exit (EXIT_FAILURE);
 return sock;
```

Here is another example, showing how you can fill in a sockaddr_in structure, given a host name string and a port number:

```
name->sin_family = AF_INET;
name->sin_port = htons (port);
hostinfo = gethostbyname (serverhost);
if (hostinfo == NULL)
    {
        fprintf (stderr, "Unknown host %s.\n", hostname);
        exit (EXIT_FAILURE);
     }
    name->sin_addr = *(struct in_addr *) hostinfo->h_addr;
}
```

15.6 Other Namespaces

Certain other namespaces and associated protocol families are supported but not documented yet because they are not often used. PF_NS refers to the Xerox Network Software protocols. PF_ISO stands for Open Systems Interconnect. PF_CCITT refers to protocols from CCITT. 'socket.h' defines these symbols and others naming protocols not actually implemented.

PF_IMPLINK is used for communicating between hosts and Internet Message Processors. For information on this, and on PF_ROUTE, an occasionally-used local area routing protocol, see the GNU Hurd Manual (to appear in the future).

15.7 Opening and Closing Sockets

This section describes the actual library functions for opening and closing sockets. The same functions work for all namespaces and connection styles.

15.7.1 Creating a Socket

The primitive for creating a socket is the socket function, declared in 'sys/socket.h'.

```
int socket (int namespace, int style, int protocol)
```

Function

This function creates a socket and specifies communication style *style*, which should be one of the socket styles listed in Section 15.2 [Communication Styles], page 270. The *namespace* argument specifies the namespace; it must be PF_FILE (see Section 15.4 [File Namespace], page 275) or PF_INET (see Section 15.5 [Internet Namespace], page 278).

protocol designates the specific protocol (see Section 15.1 [Socket Concepts], page 269); zero is usually right for protocol.

The return value from **socket** is the file descriptor for the new socket, or -1 in case of error. The following **error** error conditions are defined for this function:

EPROTONOSUPPORT

The protocol or style is not supported by the namespace specified.

EMFILE The process already has too many file descriptors open.

ENFILE The system already has too many file descriptors open.

EACCESS The process does not have privilege to create a socket of the specified style

or protocol.

ENOBUFS The system ran out of internal buffer space.

The file descriptor returned by the **socket** function supports both read and write operations. But, like pipes, sockets do not support file positioning operations.

For examples of how to call the **socket** function, see Section 15.4 [File Namespace], page 275, or Section 15.5.7 [Inet Example], page 290.

15.7.2 Closing a Socket

When you are finished using a socket, you can simply close its file descriptor with close; see Section 12.1 [Opening and Closing Files], page 203. If there is still data waiting to be transmitted over the connection, normally close tries to complete this transmission. You can control this behavior using the SO_LINGER socket option to specify a timeout period; see Section 15.11 [Socket Options], page 316.

You can also shut down only reception or only transmission on a connection by calling shutdown, which is declared in 'sys/socket.h'.

int shutdown (int socket, int how)

Function

The **shutdown** function shuts down the connection of socket *socket*. The argument *how* specifies what action to perform:

- O Stop receiving data for this socket. If further data arrives, reject it.
- Stop trying to transmit data from this socket. Discard any data waiting to be sent. Stop looking for acknowledgement of data already sent; don't retransmit it if it is lost.
- 2 Stop both reception and transmission.

The return value is 0 on success and -1 on failure. The following errno error conditions are defined for this function:

 ${\tt EBADF} \qquad \qquad socket \ {\rm is \ not \ a \ valid \ file \ descriptor}.$

ENOTSOCK socket is not a socket.

ENOTCONN socket is not connected.

15.7.3 Socket Pairs

A socket pair consists of a pair of connected (but unnamed) sockets. It is very similar to a pipe and is used in much the same way. Socket pairs are created with the socketpair function, declared in 'sys/socket.h'. A socket pair is much like a pipe; the main difference is that the socket pair is bidirectional, whereas the pipe has one input-only end and one output-only end (see Chapter 14 [Pipes and FIFOs], page 263).

int socketpair (int namespace, int style, int protocol, int filedes[2]) Function This function creates a socket pair, returning the file descriptors in filedes[0] and filedes[1]. The socket pair is a full-duplex communications channel, so that both reading and writing may be performed at either end.

The namespace, style, and protocol arguments are interpreted as for the socket function. style should be one of the communication styles listed in Section 15.2 [Communication Styles], page 270. The namespace argument specifies the namespace, which must be AF_FILE (see Section 15.4 [File Namespace], page 275); protocol specifies the communications protocol, but zero is the only meaningful value.

If *style* specifies a connectionless communication style, then the two sockets you get are not *connected*, strictly speaking, but each of them knows the other as the default destination address, so they can send packets to each other.

The socketpair function returns 0 on success and -1 on failure. The following errno error conditions are defined for this function:

EMFILE The process has too many file descriptors open.

EAFNOSUPPORT

The specified namespace is not supported.

EPROTONOSUPPORT

The specified protocol is not supported.

EOPNOTSUPP

The specified protocol does not support the creation of socket pairs.

15.8 Using Sockets with Connections

The most common communication styles involve making a connection to a particular other socket, and then exchanging data with that socket over and over. Making a connection is asymmetric; one side (the *client*) acts to request a connection, while the other side (the *server*) makes a socket and waits for the connection request.

- Section 15.8.1 [Connecting], page 295, describes what the client program must do to initiate a connection with a server.
- Section 15.8.2 [Listening], page 296, and Section 15.8.3 [Accepting Connections], page 297, describe what the server program must do to wait for and act upon connection requests from clients.
- Section 15.8.5 [Transferring Data], page 299, describes how data is transferred through the connected socket.

15.8.1 Making a Connection

In making a connection, the client makes a connection while the server waits for and accepts the connection. Here we discuss what the client program must do, using the connect function.

 $int connect (int socket, struct sockaddr *addr, size_t length)$ Function

The connect function initiates a connection from the socket with file descriptor socket to the socket whose address is specified by the addr and length arguments. (This socket is typically on another machine, and it must be already set up as a server.) See

Section 15.3 [Socket Addresses], page 271, for information about how these arguments are interpreted.

Normally, connect waits until the server responds to the request before it returns. You can set nonblocking mode on the socket socket to make connect return immediately without waiting for the response. See Section 12.10 [File Status Flags], page 224, for information about nonblocking mode.

The normal return value from connect is 0. If an error occurs, connect returns -1. The following error conditions are defined for this function:

EBADF The socket socket is not a valid file descriptor.

ENOTSOCK The socket socket is not a socket.

EADDRNOTAVAIL

The specified address is not available on the remote machine.

EAFNOSUPPORT

The namespace of the addr is not supported by this socket.

EISCONN The socket socket is already connected.

ETIMEDOUT

The attempt to establish the connection timed out.

ECONNREFUSED

The server has actively refused to establish the connection.

ENETUNREACH

The network of the given addr isn't reachable from this host.

EADDRINUSE

The socket address of the given addr is already in use.

EINPROGRESS

The socket is non-blocking and the connection could not be established immediately.

EALREADY The socket socket is non-blocking and already has a pending connection in progress.

15.8.2 Listening for Connections

Now let us consider what the server process must do to accept connections on a socket. This involves the use of the listen function to enable connection requests on the socket, and later using

the accept function (see Section 15.8.3 [Accepting Connections], page 297) to act on a request. The listen function is not allowed for sockets using connectionless communication styles.

You can write a network server that does not even start running until a connection to it is requested. See Section 15.10.1 [Inetd Servers], page 314.

In the Internet namespace, there are no special protection mechanisms for controlling access to connect to a port; any process on any machine can make a connection to your server. If you want to restrict access to your server, make it examine the addresses associated with connection requests or implement some other handshaking or identification protocol.

In the File namespace, the ordinary file protection bits control who has access to connect to the socket.

int listen (int socket, unsigned int n)

Function

The listen function enables the socket socket to accept connections, thus making it a server socket.

The argument n specifies the length of the queue for pending connections.

The listen function returns 0 on success and -1 on failure. The following errno error conditions are defined for this function:

EBADF The argument socket is not a valid file descriptor.

ENOTSOCK The argument socket is not a socket.

EOPNOTSUPP

The socket socket does not support this operation.

15.8.3 Accepting Connections

When a server receives a connection request, it can complete the connection by accepting the request. Use the function accept to do this.

A socket that has been established as a server can accept connection requests from multiple clients. The server's original socket does not become part of the connection; instead, accept makes a new socket which participates in the connection. accept returns the descriptor for this socket. The server's original socket remains available for listening for further connection requests.

The number of pending connection requests on a server socket is finite. If connection requests arrive from clients faster than the server can act upon them, the queue can fill up and additional requests are refused with a ECONNREFUSED error. You can specify the maximum length of this queue as an argument to the listen function, although the system may also impose its own internal limit on the length of this queue.

int accept (int socket, struct sockaddr *addr, size_t *length ptr) Function

This function is used to accept a connection request on the server socket socket.

The accept function waits if there are no connections pending, unless the socket socket has nonblocking mode set. (You can use select to wait for a pending connection, with a nonblocking socket.) See Section 12.10 [File Status Flags], page 224, for information about nonblocking mode.

The addr and length_ptr arguments are used to return information about the name of the client socket that initiated the connection. See Section 15.3 [Socket Addresses], page 271, for information about the format of the information.

Accepting a connection does not make *socket* part of the connection. Instead, it creates a new socket which becomes connected. The normal return value of accept is the file descriptor for the new socket.

After accept, the original socket socket remains open and unconnected, and continues listening until you close it. You can accept further connections with socket by calling accept again.

If an error occurs, accept returns -1. The following error conditions are defined for this function:

EBADF The socket argument is not a valid file descriptor.

ENOTSOCK The descriptor socket argument is not a socket.

EOPNOTSUPP

The descriptor socket does not support this operation.

EWOULDBLOCK

socket has nonblocking mode set, and there are no pending connections immediately available.

The accept function is not allowed for sockets using connectionless communication styles.

15.8.4 Who is Connected to Me?

The getpeername function returns the address of the socket that socket is connected to; it stores the address in the memory space specified by addr and length_ptr. It stores the length of the address in *length ptr.

See Section 15.3 [Socket Addresses], page 271, for information about the format of the address. In some operating systems, getpeername works only for sockets in the Internet domain.

The return value is 0 on success and -1 on error. The following error conditions are defined for this function:

EBADF The argument socket is not a valid file descriptor.

ENOTSOCK The descriptor socket is not a socket.

ENOTCONN The socket socket is not connected.

ENOBUFS There are not enough internal buffers available.

15.8.5 Transferring Data

Once a socket has been connected to a peer, you can use the ordinary read and write operations (see Section 12.2 [I/O Primitives], page 206) to transfer data. A socket is a two-way communications channel, so read and write operations can be performed at either end.

There are also some I/O modes that are specific to socket operations. In order to specify these modes, you must use the recv and send functions instead of the more generic read and write functions. The recv and send functions take an additional argument which you can use to specify various flags to control the special I/O modes. For example, you can specify the MSG_OOB flag to read or write out-of-band data, the MSG_PEEK flag to peek at input, or the MSG_DONTROUTE flag to control inclusion of routing information on output.

The GNU C Library

15.8.5.1 Sending Data

The send function is declared in the header file 'sys/socket.h'. If your flags argument is zero, you can just as well use write instead of send; see Section 12.2 [I/O Primitives], page 206. If the socket was connected but the connection has broken, you get a SIGPIPE signal for any use of send or write (see Section 21.2.6 [Miscellaneous Signals], page 414).

int send (int socket, void *buffer, size_t size, int flags)

Function

The send function is like write, but with the additional flags flags. The possible values of flags are described in Section 15.8.5.3 [Socket Data Options], page 301.

This function returns the number of bytes transmitted, or -1 on failure. If the socket is nonblocking, then send (like write) can return after sending just part of the data. See Section 12.10 [File Status Flags], page 224, for information about nonblocking mode.

Note, however, that a successful return value merely indicates that the message has been sent without error, not necessarily that it has been received without error.

The following errno error conditions are defined for this function:

EBADF The socket argument is not a valid file descriptor.

EINTR The operation was interrupted by a signal before any data was sent. See Section 21.5 [Interrupted Primitives], page 438.

ENOTSOCK The descriptor socket is not a socket.

EMSGSIZE The socket type requires that the message be sent atomically, but the message is too large for this to be possible.

EWOULDBLOCK

Nonblocking mode has been set on the socket, and the write operation would block. (Normally send blocks until the operation can be completed.)

ENOBUFS There is not enough internal buffer space available.

ENOTCONN You never connected this socket.

EPIPE This socket was connected but the connection is now broken. In this case, send generates a SIGPIPE signal first; if that signal is ignored or blocked, or if its handler returns, then send fails with EPIPE.

15.8.5.2 Receiving Data

The recv function is declared in the header file 'sys/socket.h'. If your flags argument is zero, you can just as well use read instead of recv; see Section 12.2 [I/O Primitives], page 206.

int recv (int socket, void *buffer, size_t size, int flags)

Function

The recv function is like read, but with the additional flags flags. The possible values of flags are described In Section 15.8.5.3 [Socket Data Options], page 301.

If nonblocking mode is set for *socket*, and no data is available to be read, recv fails immediately rather than waiting. See Section 12.10 [File Status Flags], page 224, for information about nonblocking mode.

This function returns the number of bytes received, or -1 on failure. The following errno error conditions are defined for this function:

EBADF The socket argument is not a valid file descriptor.

ENOTSOCK The descriptor socket is not a socket.

EWOULDBLOCK

Nonblocking mode has been set on the socket, and the read operation would block. (Normally, recv blocks until there is input available to be read.)

EINTR The operation was interrupted by a signal before any data was read. See Section 21.5 [Interrupted Primitives], page 438.

ENOTCONN You never connected this socket.

15.8.5.3 Socket Data Options

The flags argument to send and recv is a bit mask. You can bitwise-OR the values of the following macros together to obtain a value for this argument. All are defined in the header file 'sys/socket.h'.

int MSG_OOB Macro

Send or receive out-of-band data. See Section 15.8.8 [Out-of-Band Data], page 306.

int MSG_PEEK Macro

Look at the data but don't remove it from the input queue. This is only meaningful with input functions such as recv, not with send.

int MSG_DONTROUTE

Macro

Don't include routing information in the message. This is only meaningful with output operations, and is usually only of interest for diagnostic or routing programs. We don't try to explain it here.

15.8.6 Byte Stream Socket Example

Here is an example client program that makes a connection for a byte stream socket in the Internet namespace. It doesn't do anything particularly interesting once it has connected to the server; it just sends a text string to the server and exits.

```
#include <stdio.h>
#include <errno.h>
#include <stdlib.h>
#include <unistd.h>
#include <sys/types.h>
#include <sys/socket.h>
#include <netinet/in.h>
#include <netdb.h>
#define PORT 5555
#define MESSAGE "Yow!!! Are we having fun yet?!?"
#define SERVERHOST "churchy.gnu.ai.mit.edu"
void
write_to_server (int filedes)
  int nbytes;
 nbytes = write (filedes, MESSAGE, strlen (MESSAGE) + 1);
  if (nbytes < 0)
      perror ("write");
      exit (EXIT_FAILURE);
}
int
main (void)
```

```
extern void init_sockaddr (struct sockaddr_in *name,
     const char *hostname, unsigned short int port);
  int sock;
  struct sockaddr_in servername;
  /* Create the socket. */
  sock = socket (PF_INET, SOCK_STREAM, 0);
  if (sock < 0)
    {
      perror ("socket (client)");
      exit (EXIT_FAILURE);
  /* Connect to the server. */
  init_sockaddr (&servername, SERVERHOST, PORT);
  if (0 > connect (sock,
   (struct sockaddr *) &servername,
   sizeof (servername)))
      perror ("connect (client)");
      exit (EXIT_FAILURE);
  /* Send data to the server.
  write_to_server (sock);
  close (sock);
  exit (EXIT_SUCCESS);
}
```

15.8.7 Byte Stream Connection Server Example

The server end is much more complicated. Since we want to allow multiple clients to be connected to the server at the same time, it would be incorrect to wait for input from a single client by simply calling read or recv. Instead, the right thing to do is to use select (see Section 12.6 [Waiting for I/O], page 215) to wait for input on all of the open sockets. This also allows the server to deal with additional connection requests.

This particular server doesn't do anything interesting once it has gotten a message from a client. It does close the socket for that client when it detects an end-of-file condition (resulting from the client shutting down its end of the connection).

This program uses make_socket and init_sockaddr to set up the socket address; see Section 15.5.7 [Inet Example], page 290.

```
#include <stdio.h>
#include <errno.h>
#include <stdlib.h>
#include <unistd.h>
#include <sys/types.h>
#include <sys/socket.h>
#include <netinet/in.h>
#include <netdb.h>
#define PORT 5555
#define MAXMSG 512
read_from_client (int filedes)
  char buffer[MAXMSG];
  int nbytes;
  nbytes = read (filedes, buffer, MAXMSG);
  if (nbytes < 0)
    {
      /* Read error. */
      perror ("read");
      exit (EXIT_FAILURE);
    }
  else if (nbytes == 0)
    /* End-of-file. */
    return -1;
  else
    {
      /* Data read. */
      fprintf (stderr, "Server: got message: '%s'\n", buffer);
      return 0;
    }
}
int
main (void)
  extern int make_socket (unsigned short int port);
  int sock;
  int status;
  fd_set active_fd_set, read_fd_set;
  struct sockaddr_in clientname;
  size_t size;
```

```
/* Create the socket and set it up to accept connections. */
  sock = make_socket (PORT);
  if (listen (sock, 1) < 0)
      perror ("listen");
      exit (EXIT_FAILURE);
  /* Initialize the set of active sockets. */
  FD_ZERO (&active_fd_set);
  FD_SET (sock, &active_fd_set);
  while (1)
    {
      /* Block until input arrives on one or more active sockets. */
      read_fd_set = active_fd_set;
      if (select (FD_SETSIZE, &read_fd_set, NULL, NULL, NULL) < 0)
{
 perror ("select");
 exit (EXIT_FAILURE);
}
      /* Service all the sockets with input pending. */
      for (i = 0; i < FD_SETSIZE; ++i)</pre>
if (FD_ISSET (i, &read_fd_set))
    if (i == sock)
/* Connection request on original socket. */
size = sizeof (clientname);
if (accept (sock,
    (struct sockaddr *) &clientname, &size) < 0)
    perror ("accept");
    exit (EXIT_FAILURE);
fprintf (stderr, "Server: connect from host %s, port %hd.\n",
 inet_ntoa (clientname.sin_addr),
ntohs (clientname.sin_port));
FD_SET (status, &active_fd_set);
      }
    else
/* Data arriving on an already-connected socket. */
```

```
if (read_from_client (i) < 0)
    {
      close (i);
      FD_CLR (i, &active_fd_set);
    }
    }
}</pre>
```

15.8.8 Out-of-Band Data

Streams with connections permit *out-of-band* data that is delivered with higher priority than ordinary data. Typically the reason for sending out-of-band data is to send notice of an exceptional condition. The way to send out-of-band data is using **send**, specifying the flag MSG_00B (see Section 15.8.5.1 [Sending Data], page 300).

Out-of-band data is received with higher priority because the receiving process need not read it in sequence; to read the next available out-of-band data, use recv with the MSG_OOB flag (see Section 15.8.5.2 [Receiving Data], page 301). Ordinary read operations do not read out-of-band data; they read only the ordinary data.

When a socket finds that out-of-band data is on its way, it sends a SIGURG signal to the owner process or process group of the socket. You can specify the owner using the F_SETOWN command to the fcntl function; see Section 12.12 [Interrupt Input], page 231. You must also establish a handler for this signal, as described in Chapter 21 [Signal Handling], page 403, in order to take appropriate action such as reading the out-of-band data.

Alternatively, you can test for pending out-of-band data, or wait until there is out-of-band data, using the select function; it can wait for an exceptional condition on the socket. See Section 12.6 [Waiting for I/O], page 215, for more information about select.

Notification of out-of-band data (whether with SIGURG or with select) indicates that out-of-band data is on the way; the data may not actually arrive until later. If you try to read the out-of-band data before it arrives, recv fails with an EWOULDBLOCK error.

Sending out-of-band data automatically places a "mark" in the stream of ordinary data, showing where in the sequence the out-of-band data "would have been". This is useful when the meaning of out-of-band data is "cancel everything sent so far". Here is how you can test, in the receiving process, whether any ordinary data was sent before the mark:

```
success = ioctl (socket, SIOCATMARK, &result);
```

Here's a function to discard any ordinary data preceding the out-of-band mark:

```
int
discard_until_mark (int socket)
  while (1)
    {
      /* This is not an arbitrary limit; any size will do. */
      char buffer[1024];
      int result, success;
      /* If we have reached the mark, return. */
      success = ioctl (socket, SIOCATMARK, &result);
      if (success < 0)
        perror ("ioctl");
      if (result)
        return;
      /* Otherwise, read a bunch of ordinary data and discard it.
         This is guaranteed not to read past the mark
         if it starts before the mark. */
      success = read (socket, buffer, sizeof buffer);
      if (success < 0)
        perror ("read");
    }
}
```

If you don't want to discard the ordinary data preceding the mark, you may need to read some of it anyway, to make room in internal system buffers for the out-of-band data. If you try to read out-of-band data and get an EWOULDBLOCK error, try reading some ordinary data (saving it so that you can use it when you want it) and see if that makes room. Here is an example:

```
struct buffer
{
   char *buffer;
   int size;
   struct buffer *next;
};

/* Read the out-of-band data from SOCKET and return it
   as a 'struct buffer', which records the address of the data
   and its size.
```

```
It may be necessary to read some ordinary data
   in order to make room for the out-of-band data.
   If so, the ordinary data is saved as a chain of buffers
   found in the 'next' field of the value. */
struct buffer *
read_oob (int socket)
  struct buffer *tail = 0;
  struct buffer *list = 0;
  while (1)
    {
      /* This is an arbitrary limit.
         Does anyone know how to do this without a limit? */
      char *buffer = (char *) xmalloc (1024);
      struct buffer *link;
      int success;
      int result;
      /* Try again to read the out-of-band data. */
      success = recv (socket, buffer, sizeof buffer, MSG_OOB);
      if (success \geq 0)
        {
          /* We got it, so return it. */
          struct buffer *link
             = (struct buffer *) xmalloc (sizeof (struct buffer));
          link->buffer = buffer;
          link->size = success;
          link->next = list;
          return link;
        }
      /* If we fail, see if we are at the mark. */
      success = ioctl (socket, SIOCATMARK, &result);
      if (success < 0)
        perror ("ioctl");
      if (result)
        {
           /* At the mark; skipping past more ordinary data cannot help.
              So just wait a while. */
          sleep (1);
           continue;
        }
```

```
/* Otherwise, read a bunch of ordinary data and save it.
         This is guaranteed not to read past the mark
         if it starts before the mark.
      success = read (socket, buffer, sizeof buffer);
      if (success < 0)
        perror ("read");
      /* Save this data in the buffer list. */
        struct buffer *link
           = (struct buffer *) xmalloc (sizeof (struct buffer));
        link->buffer = buffer;
        link->size = success;
        /* Add the new link to the end of the list. */
         if (tail)
           tail->next = link;
         else
           list = link;
        tail = link;
      }
    }
}
```

15.9 Datagram Socket Operations

This section describes how to use communication styles that don't use connections (styles SOCK_DGRAM and SOCK_RDM). Using these styles, you group data into packets and each packet is an independent communication. You specify the destination for each packet individually.

Datagram packets are like letters: you send each one independently, with its own destination address, and they may arrive in the wrong order or not at all.

The listen and accept functions are not allowed for sockets using connectionless communication styles.

15.9.1 Sending Datagrams

The normal way of sending data on a datagram socket is by using the sendto function, declared in 'sys/socket.h'.

You can call connect on a datagram socket, but this only specifies a default destination for further data transmission on the socket. When a socket has a default destination, then you can use send (see Section 15.8.5.1 [Sending Data], page 300) or even write (see Section 12.2 [I/O Primitives], page 206) to send a packet there. You can cancel the default destination by calling connect using an address format of AF_UNSPEC in the addr argument. See Section 15.8.1 [Connecting], page 295, for more information about the connect function.

The sendto function transmits the data in the *buffer* through the socket *socket* to the destination address specified by the *addr* and *length* arguments. The *size* argument specifies the number of bytes to be transmitted.

The flags are interpreted the same way as for send; see Section 15.8.5.3 [Socket Data Options], page 301.

The return value and error conditions are also the same as for **send**, but you cannot rely on the system to detect errors and report them; the most common error is that the packet is lost or there is no one at the specified address to receive it, and the operating system on your machine usually does not know this.

It is also possible for one call to **sendto** to report an error due to a problem related to a previous call.

15.9.2 Receiving Datagrams

The recvfrom function reads a packet from a datagram socket and also tells you where it was sent from. This function is declared in 'sys/socket.h'.

The recvfrom function reads one packet from the socket socket into the buffer buffer. The size argument specifies the maximum number of bytes to be read.

If the packet is longer than size bytes, then you get the first size bytes of the packet, and the rest of the packet is lost. There's no way to read the rest of the packet. Thus, when you use a packet protocol, you must always know how long a packet to expect.

The addr and length_ptr arguments are used to return the address where the packet came from. See Section 15.3 [Socket Addresses], page 271. For a socket in the file domain, the address information won't be meaningful, since you can't read the address of such a socket (see Section 15.4 [File Namespace], page 275). You can specify a null pointer as the addr argument if you are not interested in this information.

The flags are interpreted the same way as for recv (see Section 15.8.5.3 [Socket Data Options], page 301). The return value and error conditions are also the same as for recv.

You can use plain recv (see Section 15.8.5.2 [Receiving Data], page 301) instead of recvfrom if you know don't need to find out who sent the packet (either because you know where it should come from or because you treat all possible senders alike). Even read can be used if you don't want to specify flags (see Section 12.2 [I/O Primitives], page 206).

15.9.3 Datagram Socket Example

Here is a set of example programs that send messages over a datagram stream in the file namespace. Both the client and server programs use the make_named_socket function that was presented in Section 15.4 [File Namespace], page 275, to create and name their sockets.

First, here is the server program. It sits in a loop waiting for messages to arrive, bouncing each message back to the sender. Obviously, this isn't a particularly useful program, but it does show the general ideas involved.

```
#include <stdio.h>
#include <errno.h>
#include <stdlib.h>
#include <sys/socket.h>
#include <sys/un.h>
#define SERVER "/tmp/serversocket"
#define MAXMSG 512
int
main (void)
```

```
{
  int sock;
  char message[MAXMSG];
  struct sockaddr_un name;
  size_t size;
  int nbytes;
  /* Make the socket, then loop endlessly. */
  sock = make_named_socket (SERVER);
  while (1)
      /* Wait for a datagram. */
      size = sizeof (name);
      nbytes = recvfrom (sock, message, MAXMSG, 0,
 (struct sockaddr *) & name, &size);
      if (nbytes < 0)
{
 perror ("recfrom (server)");
  exit (EXIT_FAILURE);
      /* Give a diagnostic message. */
      fprintf (stderr, "Server: got message: %s\n", message);
      /* Bounce the message back to the sender. */
      nbytes = sendto (sock, message, nbytes, 0,
       (struct sockaddr *) & name, size);
      if (nbytes < 0)
{
 perror ("sendto (server)");
  exit (EXIT_FAILURE);
}
    }
```

15.9.4 Example of Reading Datagrams

Here is the client program corresponding to the server above.

It sends a datagram to the server and then waits for a reply. Notice that the socket for the client (as well as for the server) in this example has to be given a name. This is so that the server can direct a message back to the client. Since the socket has no associated connection state, the only way the server can do this is by referencing the name of the client.

```
#include <stdio.h>
```

```
#include <errno.h>
#include <unistd.h>
#include <stdlib.h>
#include <sys/socket.h>
#include <sys/un.h>
#define SERVER "/tmp/serversocket"
#define CLIENT "/tmp/mysocket"
#define MAXMSG 512
#define MESSAGE "Yow!!! Are we having fun yet?!?"
int
main (void)
{
  extern int make_named_socket (const char *name);
  int sock;
  char message[MAXMSG];
  struct sockaddr_un name;
  size_t size;
  int nbytes;
  /* Make the socket. */
  sock = make_named_socket (CLIENT);
  /* Initialize the server socket address. */
  name.sun_family = AF_UNIX;
  strcpy (name.sun_path, SERVER);
  size = strlen (name.sun_path) + sizeof (name.sun_family);
  /* Send the datagram. */
 nbytes = sendto (sock, MESSAGE, strlen (MESSAGE) + 1, 0,
   (struct sockaddr *) & name, size);
  if (nbytes < 0)
      perror ("sendto (client)");
      exit (EXIT_FAILURE);
  /* Wait for a reply. */
  nbytes = recvfrom (sock, message, MAXMSG, 0, NULL, 0);
  if (nbytes < 0)
      perror ("recfrom (client)");
      exit (EXIT_FAILURE);
  /* Print a diagnostic message. */
  fprintf (stderr, "Client: got message: %s\n", message);
```

```
/* Clean up. */
remove (CLIENT);
close (sock);
}
```

Keep in mind that datagram socket communications are unreliable. In this example, the client program waits indefinitely if the message never reaches the server or if the server's response never comes back. It's up to the user running the program to kill it and restart it, if desired. A more automatic solution could be to use select (see Section 12.6 [Waiting for I/O], page 215) to establish a timeout period for the reply, and in case of timeout either resend the message or shut down the socket and exit.

15.10 The inetd Daemon

We've explained above how to write a server program that does its own listening. Such a server must already be running in order for anyone to connect to it.

Another way to provide service for an Internet port is to let the daemon program inetd do the listening. inetd is a program that runs all the time and waits (using select) for messages on a specified set of ports. When it receives a message, it accepts the connection (if the socket style calls for connections) and then forks a child process to run the corresponding server program. You specify the ports and their programs in the file '/etc/inetd.conf'.

15.10.1 inetd Servers

Writing a server program to be run by inetd is very simple. Each time someone requests a connection to the appropriate port, a new server process starts. The connection already exists at this time; the socket is available as the standard input descriptor and as the standard output descriptor (descriptors 0 and 1) in the server process. So the server program can begin reading and writing data right away. Often the program needs only the ordinary I/O facilities; in fact, a general-purpose filter program that knows nothing about sockets can work as a byte stream server run by inetd.

You can also use inetd for servers that use connectionless communication styles. For these servers, inetd does not try to accept a connection, since no connection is possible. It just starts

the server program, which can read the incoming datagram packet from descriptor 0. The server program can handle one request and then exit, or you can choose to write it to keep reading more requests until no more arrive, and then exit. You must specify which of these two techniques the server uses, when you configure inetd.

15.10.2 Configuring inetd

The file '/etc/inetd.conf' tells inetd which ports to listen to and what server programs to run for them. Normally each entry in the file is one line, but you can split it onto multiple lines provided all but the first line of the entry start with whitespace. Lines that start with '#' are comments.

Here are two standard entries in '/etc/inetd.conf':

ftp stream tcp nowait root /libexec/ftpd ftpd talk dgram udp wait root /libexec/talkd talkd

An entry has this format:

service style protocol wait username program arguments

The service field says which service this program provides. It should be the name of a service defined in '/etc/services'. inetd uses service to decide which port to listen on for this entry.

The fields style and protocol specify the communication style and the protocol to use for the listening socket. The style should be the name of a communication style, converted to lower case and with 'SOCK_' deleted—for example, 'stream' or 'dgram'. protocol should be one of the protocols listed in '/etc/protocols'. The typical protocol names are 'tcp' for byte stream connections and 'udp' for unreliable datagrams.

The wait field should be either 'wait' or 'nowait'. Use 'wait' if style is a connectionless style and the server, once started, handles multiple requests, as many as come in. Use 'nowait' if inetd should start a new process for each message or request that comes in. If style uses connections, then wait must be 'nowait'.

user is the user name that the server should run as. inetd runs as root, so it can set the user ID of its children arbitrarily. It's best to avoid using 'root' for user if you can; but some servers, such as Telnet and FTP, read a username and password themselves. These servers need to be root initially so they can log in as commanded by the data coming over the network.

program together with arguments specifies the command to run to start the server. program should be an absolute file name specifying the executable file to run. arguments consists of any number of whitespace-separated words, which become the command-line arguments of program. The first word in arguments is argument zero, which should by convention be the program name itself (sans directories).

If you edit '/etc/inetd.conf', you can tell inetd to reread the file and obey its new contents by sending the inetd process the SIGHUP signal. You'll have to use ps to determine the process ID of the inetd process, as it is not fixed.

15.11 Socket Options

316

This section describes how to read or set various options that modify the behavior of sockets and their underlying communications protocols.

When you are manipulating a socket option, you must specify which *level* the option pertains to. This describes whether the option applies to the socket interface, or to a lower-level communications protocol interface.

15.11.1 Socket Option Functions

Here are the functions for examining and modifying socket options. They are declared in 'sys/socket.h'.

The getsockopt function gets information about the value of option optname at level level for socket socket.

The option value is stored in a buffer that *optval* points to. Before the call, you should supply in *optlen ptr the size of this buffer; on return, it contains the number of bytes of information actually stored in the buffer.

Most options interpret the optval buffer as a single int value.

The actual return value of getsockopt is 0 on success and -1 on failure. The following errno error conditions are defined:

EBADF The socket argument is not a valid file descriptor.

ENOTSOCK The descriptor socket is not a socket.

ENOPROTOOPT

The optname doesn't make sense for the given level.

This function is used to set the socket option optname at level level for socket socket. The value of the option is passed in the buffer optval, which has size optlen.

The return value and error codes are the same as for getsockopt.

15.11.2 Socket-Level Options

int SOL_SOCKET Constant

Use this constant as the *level* argument to getsockopt or setsockopt to manipulate the socket-level options described in this section.

Here is a table of socket-level option names; all are defined in the header file 'sys/socket.h'.

SO_DEBUG

This option toggles recording of debugging information in the underlying protocol modules. The value has type int; a nonzero value means "yes".

SO_REUSEADDR

This option controls whether bind (see Section 15.3.2 [Setting Address], page 273) should permit reuse of local addresses for this socket. If you enable this option, you

318 The GNU C Library

can actually have two sockets with the same Internet port number; but the system won't allow you to use the two identically-named sockets in a way that would confuse the Internet. The reason for this option is that some higher-level Internet protocols, including FTP, require you to keep reusing the same socket number.

The value has type int; a nonzero value means "yes".

SO_KEEPALIVE

This option controls whether the underlying protocol should periodically transmit messages on a connected socket. If the peer fails to respond to these messages, the connection is considered broken. The value has type int; a nonzero value means "yes".

SO_DONTROUTE

This option controls whether outgoing messages bypass the normal message routing facilities. If set, messages are sent directly to the network interface instead. The value has type int; a nonzero value means "yes".

SO_LINGER

This option specifies what should happen when the socket of a type that promises reliable delivery still has untransmitted messages when it is closed; see Section 15.7.2 [Closing a Socket], page 293. The value has type struct linger.

struct linger Data Type

This structure type has the following members:

int l_onoff

This field is interpreted as a boolean. If nonzero, close blocks until the data is transmitted or the timeout period has expired.

int l_linger

This specifies the timeout period, in seconds.

SO_BROADCAST

This option controls whether datagrams may be broadcast from the socket. The value has type int; a nonzero value means "yes".

SO_OOBINLINE

If this option is set, out-of-band data received on the socket is placed in the normal input queue. This permits it to be read using read or recv without specifying the MSG_OOB flag. See Section 15.8.8 [Out-of-Band Data], page 306. The value has type int; a nonzero value means "yes".

SO_SNDBUF

This option gets or sets the size of the output buffer. The value is an size_t, which is the size in bytes.

SO_RCVBUF

This option gets or sets the size of the input buffer. The value is an size_t, which is the size in bytes.

SO_STYLE

This option can be used with getsockopt only. It is used to get the socket's communication style. SO_TYPE is the historical name, and SO_STYLE is the preferred name in GNU. The value has type int and its value designates a communication style; see Section 15.2 [Communication Styles], page 270.

SO_ERROR

This option can be used with getsockopt only. It is used to reset the error status of the socket. The value is an int, which represents the previous error status.

15.12 Networks Database

Many systems come with a database that records a list of networks known to the system developer. This is usually kept either in the file '/etc/networks' or in an equivalent from a name server. This data base is useful for routing programs such as route, but it is not useful for programs that simply communicate over the network. We provide functions to access this data base, which are declared in 'netdb.h'.

struct netent Data Type

This data type is used to represent information about entries in the networks database. It has the following members:

char *n_name

This is the "official" name of the network.

char **n_aliases

These are alternative names for the network, represented as a vector of strings. A null pointer terminates the array.

int n_addrtype

This is the type of the network number; this is always equal to AF_INET for Internet networks.

unsigned long int n_net

This is the network number. Network numbers are returned in host byte order; see Section 15.5.5 [Byte Order], page 287.

The GNU C Library

Use the getnetbyname or getnetbyaddr functions to search the networks database for information about a specific network. The information is returned in a statically-allocated structure; you must copy the information if you need to save it.

struct netent * getnetbyname (const char *name)

Function

The getnetbyname function returns information about the network named name. It returns a null pointer if there is no such network.

struct netent * getnetbyaddr (long net, int type)

Function

The getnetbyaddr function returns information about the network of type type with number net. You should specify a value of AF_INET for the type argument for Internet networks.

getnetbyaddr returns a null pointer if there is no such network.

You can also scan the networks database using setnetent, getnetent, and endnetent. Be careful in using these functions, because they are not reentrant.

void setnetent (int stayopen)

320

Function

This function opens and rewinds the networks database.

If the *stayopen* argument is nonzero, this sets a flag so that subsequent calls to **getnetbyname** or **getnetbyaddr** will not close the database (as they usually would). This makes for more efficiency if you call those functions several times, by avoiding reopening the database for each call.

struct netent * getnetent (void)

Function

This function returns the next entry in the networks database. It returns a null pointer if there are no more entries.

void endnetent (void)

Function

This function closes the networks database.

16 Low-Level Terminal Interface

This chapter describes functions that are specific to terminal devices. You can use these functions to do things like turn off input echoing; set serial line characteristics such as line speed and flow control; and change which characters are used for end-of-file, command-line editing, sending signals, and similar control functions.

Most of the functions in this chapter operate on file descriptors. See Chapter 12 [Low-Level I/O], page 203, for more information about what a file descriptor is and how to open a file descriptor for a terminal device.

16.1 Identifying Terminals

The functions described in this chapter only work on files that correspond to terminal devices. You can find out whether a file descriptor is associated with a terminal by using the isatty function.

Prototypes for both isatty and ttyname are declared in the header file 'unistd.h'.

int isatty (int filedes)

Function

This function returns 1 if filedes is a file descriptor associated with an open terminal device, and 0 otherwise.

If a file descriptor is associated with a terminal, you can get its associated file name using the ttyname function. See also the ctermid function, described in Section 24.7.1 [Identifying the Terminal], page 516.

char * ttyname (int filedes)

Function

If the file descriptor filedes is associated with a terminal device, the ttyname function returns a pointer to a statically-allocated, null-terminated string containing the file name of the terminal file. The value is a null pointer if the file descriptor isn't associated with a terminal, or the file name cannot be determined.

322 The GNU C Library

16.2 I/O Queues

Many of the remaining functions in this section refer to the input and output queues of a terminal device. These queues implement a form of buffering within the kernel independent of the buffering implemented by I/O streams (see Chapter 11 [I/O on Streams], page 139).

The terminal input queue is also sometimes referred to as its typeahead buffer. It holds the characters that have been received from the terminal but not yet read by any process.

The size of the terminal's input queue is described by the _POSIX_MAX_INPUT and MAX_INPUT parameters; see Section 27.6 [Limits for Files], page 553. If input flow control is enabled by setting the IXOFF input mode bit (see Section 16.4.4 [Input Modes], page 327), the terminal driver transmits STOP and START characters to the terminal when necessary to prevent the queue from overflowing. Otherwise, input may be lost if it comes in too fast from the terminal. (This is unlikely if you are typing the input by hand!)

The terminal output queue is like the input queue, but for output; it contains characters that have been written by processes, but not yet transmitted to the terminal. If output flow control is enabled by setting the IXON input mode bit (see Section 16.4.4 [Input Modes], page 327), the terminal driver obeys STOP and STOP characters sent by the terminal to stop and restart transmission of output.

Clearing the terminal input queue means discarding any characters that have been received but not yet read. Similarly, clearing the terminal output queue means discarding any characters that have been written but not yet transmitted.

16.3 Two Styles of Input: Canonical or Not

POSIX systems support two basic modes of input: canonical and noncanonical.

In canonical input processing mode, terminal input is processed in lines terminated by newline ('\n'), EOF, or EOL characters. No input can be read until an entire line has been typed by the user, and the read function (see Section 12.2 [I/O Primitives], page 206) returns at most a single line of input, no matter how many bytes are requested.

In canonical input mode, the operating system provides input editing facilities: the ERASE and KILL characters are interpreted specially to perform editing operations within the current line of text. See Section 16.4.9.1 [Editing Characters], page 336.

The constants _POSIX_MAX_CANON and MAX_CANON parameterize the maximum number of bytes which may appear in a single line of canonical input. See Section 27.6 [Limits for Files], page 553.

In noncanonical input processing mode, characters are not grouped into lines, and ERASE and KILL processing is not performed. The granularity with which bytes are read in noncanonical input mode is controlled by the MIN and TIME settings. See Section 16.4.10 [Noncanonical Input], page 341.

Most programs use canonical input mode, because this gives the user a way to edit input line by line. The usual reason to use noncanonical mode is when the program accepts single-character commands or provides its own editing facilities.

The choice of canonical or noncanonical input is controlled by the ICANON flag in the c_lflag member of struct termios. See Section 16.4.7 [Local Modes], page 331.

16.4 Terminal Modes

This section describes the various terminal attributes that control how input and output are done. The functions, data structures, and symbolic constants are all declared in the header file 'termios.h'.

16.4.1 Terminal Mode Data Types

The entire collection of attributes of a terminal is stored in a structure of type struct termios. This structure is used with the functions togetattr and tosetattr to read and set the attributes.

struct termios Data Type

Structure that records all the I/O attributes of a terminal. The structure includes at least the following members:

tcflag_t c_iflag

A bit mask specifying input modes; see Section 16.4.4 [Input Modes], page 327.

tcflag_t c_oflag

A bit mask specifying output modes; see Section 16.4.5 [Output Modes], page 329.

324 The GNU C Library

tcflag_t c_cflag

A bit mask specifying control modes; see Section 16.4.6 [Control Modes], page 330.

tcflag_t c_lflag

A bit mask specifying flags for local modes; see Section 16.4.7 [Local Modes], page 331.

cc_t c_cc[NCCS]

An array specifying which characters are associated with various control functions; see Section 16.4.9 [Special Characters], page 335.

The struct termios structure also contains members which encode input and output transmission speeds, but the representation is not specified. See Section 16.4.8 [Line Speed], page 333, for how to examine and store the speed values.

The following sections describe the details of the members of the struct termios structure.

tcflag_t Data Type

This is an unsigned integer type used to represent the various bit masks for terminal flags.

cc_t Data Type

This is an unsigned integer type used to represent characters associated with various terminal control functions.

int NCCS Macro

The value of this macro is the number of elements in the c_cc array.

16.4.2 Terminal Mode Functions

int tcgetattr (int filedes, struct termios *termios p)

Function

This function is used to examine the attributes of the terminal device with file descriptor filedes. The attributes are returned in the structure that termios_p points to.

If successful, tcgetattr returns 0. A return value of -1 indicates an error. The following error conditions are defined for this function:

EBADF The filedes argument is not a valid file descriptor.

ENOTTY The *filedes* is not associated with a terminal.

int tcsetattr (int filedes, int when, const struct termios *termios'p)

Function

This function sets the attributes of the terminal device with file descriptor filedes. The new attributes are taken from the structure that termios_p points to.

The when argument specifies how to deal with input and output already queued. It can be one of the following values:

TCSANOW Make the change immediately.

TCSADRAIN

Make the change after waiting until all queued output has been written. You should usually use this option when changing parameters that affect output.

TCSAFLUSH

This is like TCSADRAIN, but also discards any queued input.

TCSASOFT This is a flag bit that you can add to any of the above alternatives. Its meaning is to inhibit alteration of the state of the terminal hardware. It is a BSD extension; it has no effect on non-BSD systems.

If this function is called from a background process on its controlling terminal, normally all processes in the process group are sent a SIGTTOU signal, in the same way as if the process were trying to write to the terminal. The exception is if the calling process itself is ignoring or blocking SIGTTOU signals, in which case the operation is performed and no signal is sent. See Chapter 24 [Job Control], page 495.

If successful, tcsetattr returns 0. A return value of -1 indicates an error. The following error conditions are defined for this function:

EBADF The filedes argument is not a valid file descriptor.

ENOTTY The filedes is not associated with a terminal.

EINVAL Either the value of the when argument is not valid, or there is something wrong with the data in the termios_p argument.

Although tcgetattr and tcsetattr specify the terminal device with a file descriptor, the attributes are those of the terminal device itself and not of the file descriptor. This means that the effects of changing terminal attributes are persistent; if another process opens the terminal file later on, it will see the changed attributes even though it doesn't have anything to do with the open file descriptor you originally specified in changing the attributes.

Similarly, if a single process has multiple or duplicated file descriptors for the same terminal device, changing the terminal attributes affects input and output to all of these file descriptors. This means, for example, that you can't open one file descriptor or stream to read from a terminal in the normal line-buffered, echoed mode; and simultaneously have another file descriptor for the same terminal that you use to read from it in single-character, non-echoed mode. Instead, you have to explicitly switch the terminal back and forth between the two modes.

16.4.3 Setting Terminal Modes Properly

When you set terminal modes, you should call tcgetattr first to get the current modes of the particular terminal device, modify only those modes that you are really interested in, and store the result with tcsetattr.

It's a bad idea to simply initialize a struct termios structure to a chosen set of attributes and pass it directly to tcsetattr. Your program may be run years from now, on systems that support members not documented in this manual. The way to avoid setting these members to unreasonable values is to avoid changing them.

What's more, different terminal devices may require different mode settings in order to function properly. So you should avoid blindly copying attributes from one terminal device to another.

When a member contains a collection of independent flags, as the c_iflag, c_oflag and c_cflag members do, even setting the entire member is a bad idea, because particular operating systems have their own flags. Instead, you should start with the current value of the member and alter only the flags whose values matter in your program, leaving any other flags unchanged.

Here is an example of how to set one flag (ISTRIP) in the struct termios structure while properly preserving all the other data in the structure:

```
int
set_istrip (int desc, int value)
  struct termios settings;
  int result;
  result = tcgetattr (desc, &settings);
  if (result < 0)
    {
      perror ("error in tcgetattr");
      return 0;
    }
  settings.c_iflag &= ~ISTRIP;
  if (value)
    settings.c_iflag |= ISTRIP;
  result = tcgetattr (desc, &settings);
  if (result < 0)
    {
      perror ("error in tcgetattr");
      return;
   }
 return 1;
}
```

16.4.4 Input Modes

This section describes the terminal attribute flags that control fairly low-level aspects of input processing: handling of parity errors, break signals, flow control, and RET and LFD characters.

All of these flags are bits in the c_iflag member of the struct termios structure. The member is an integer, and you change flags using the operators &, | and ^. Don't try to specify the entire value for c_iflag—instead, change only specific flags and leave the rest untouched (see Section 16.4.3 [Setting Modes], page 326).

INPCK If this bit is set, input parity checking is enabled. If it is not set, no checking at all is done for parity errors on input; the characters are simply passed through to the application.

Parity checking on input processing is independent of whether parity detection and generation on the underlying terminal hardware is enabled; see Section 16.4.6 [Control Modes], page 330. For example, you could clear the INPCK input mode flag and set the PARENB control mode flag to ignore parity errors on input, but still generate parity on output.

If this bit is set, what happens when a parity error is detected depends on whether the IGNPAR or PARMRK bits are set. If neither of these bits are set, a byte with a parity error is passed to the application as a '\0' character.

IGNPAR If this bit is set, any byte with a framing or parity error is ignored. This is only useful if INPCK is also set.

PARMRK If this bit is set, input bytes with parity or framing errors are marked when passed to the program. This bit is meaningful only when INPCK is set and IGNPAR is not set.

The way erroneous bytes are marked is with two preceding bytes, 377 and 0. Thus, the program actually reads three bytes for one erroneous byte received from the terminal.

If a valid byte has the value 0377, and ISTRIP (see below) is not set, the program might confuse it with the prefix that marks a parity error. So a valid byte 0377 is passed to the program as two bytes, 0377 0377, in this case.

ISTRIP If this bit is set, valid input bytes are stripped to seven bits; otherwise, all eight bits are available for programs to read.

IGNBRK If this bit is set, break conditions are ignored.

A break condition is defined in the context of asynchronous serial data transmission as a series of zero-value bits longer than a single byte.

BRKINT If this bit is set and IGNBRK is not set, a break condition clears the terminal input and output queues and raises a SIGINT signal for the foreground process group associated with the terminal.

If neither BRKINT nor IGNBRK are set, a break condition is passed to the application as a single '\0' character if PARMRK is not set, or otherwise as a three-character sequence '\377', '\0', '\0'.

IGNCR If this bit is set, carriage return characters ('\r') are discarded on input. Discarding carriage return may be useful on terminals that send both carriage return and linefeed when you type the RET key.

ICRNL If this bit is set and IGNCR is not set, carriage return characters ('\r') received as input are passed to the application as newline characters ('\n').

INLCR If this bit is set, newline characters ('\n') received as input are passed to the application as carriage return characters ('\r').

IXOFF If this bit is set, start/stop control on input is enabled. In other words, the computer sends STOP and START characters as necessary to prevent input from coming in faster than programs are reading it. The idea is that the actual terminal hardware that is

generating the input data responds to a STOP character by suspending transmission, and to a START character by resuming transmission. See Section 16.4.9.4 [Start/Stop Characters], page 340.

IXON If this bit is set, start/stop control on output is enabled. In other words, if the computer receives a STOP character, it suspends output until a START character is received. In this case, the STOP and START characters are never passed to the application program. If this bit is not set, then START and STOP can be read as ordinary characters. See Section 16.4.9.4 [Start/Stop Characters], page 340.

IXANY If this bit is set, any input character restarts output when output has been suspended with the STOP character. Otherwise, only the START character restarts output.

IMAXBEL If this bit is set, then filling up the terminal input buffer sends a BEL character (code 007) to the terminal to ring the bell.

16.4.5 Output Modes

This section describes the terminal flags and fields that control how output characters are translated and padded for display. All of these are contained in the c_oflag member of the struct termios structure.

The c_oflag member itself is an integer, and you change the flags and fields using the operators &, |, and ^. Don't try to specify the entire value for c_oflag—instead, change only specific flags and leave the rest untouched (see Section 16.4.3 [Setting Modes], page 326).

int OPOST Macro

If this bit is set, output data is processed in some unspecified way so that it is displayed appropriately on the terminal device. This typically includes mapping newline characters ('\n') onto carriage return and linefeed pairs.

If this bit isn't set, the characters are transmitted as-is.

The following three bits are BSD features, and they have no effect on non-BSD systems. On all systems, they are effective only if OPOST is set.

int ONLCR Macro

If this bit is set, convert the newline character on output into a pair of characters, carriage return followed by linefeed.

int OXTABS Macro

If this bit is set, convert tab characters on output into the appropriate number of spaces to emulate a tab stop every eight columns.

int ONOEOT Macro

If this bit is set, discard C-d characters (code 004) on output. These characters cause many dial-up terminals to disconnect.

16.4.6 Control Modes

This section describes the terminal flags and fields that control parameters usually associated with asynchronous serial data transmission. These flags may not make sense for other kinds of terminal ports (such as a network connection pseudo-terminal). All of these are contained in the c_cflag member of the struct termios structure.

The c_cflag member itself is an integer, and you change the flags and fields using the operators &, |, and ^. Don't try to specify the entire value for c_cflag—instead, change only specific flags and leave the rest untouched (see Section 16.4.3 [Setting Modes], page 326).

CLOCAL If this bit is set, it indicates that the terminal is connected "locally" and that the modem status lines (such as carrier detect) should be ignored.

If this bit is not set and you call open without the O_NONBLOCK flag set, open blocks until a modem connection is established.

If this bit is not set and a modem disconnect is detected, a SIGHUP signal is sent to the controlling process group for the terminal (if it has one). Normally, this causes the process to exit; see Chapter 21 [Signal Handling], page 403. Reading from the terminal after a disconnect causes an end-of-file condition, and writing causes an EIO error to be returned. The terminal device must be closed and reopened to clear the condition.

HUPCL If this bit is set, a modern disconnect is generated when all processes that have the terminal device open have either closed the file or exited.

CREAD If this bit is set, input can be read from the terminal. Otherwise, input is discarded when it arrives.

CSTOPB If this bit is set, two stop bits are used. Otherwise, only one stop bit is used.

PARENB If this bit is set, generation and detection of a parity bit are enabled. See Section 16.4.4 [Input Modes], page 327, for information on how input parity errors are handled.

If this bit is not set, no parity bit is added to output characters, and input characters are not checked for correct parity.

PARODD This bit is only useful if PARENB is set. If PARODD is set, odd parity is used, otherwise even parity is used.

The control mode flags also includes a field for the number of bits per character. You can use the CSIZE macro as a mask to extract the value, like this: settings.c_cflag & CSIZE.

CSIZE This is a mask for the number of bits per character.

CS5 This specifies five bits per byte.
CS6 This specifies six bits per byte.
CS7 This specifies seven bits per byte.

This specifies eight bits per byte.

CCTS_OFLOW

If this bit is set, enable flow control of output based on the CTS wire (RS232 protocol).

CRTS_IFLOW

If this bit is set, enable flow control of input based on the RTS wire (RS232 protocol).

MDMBUF If this bit is set, enable carrier-based flow control of output.

16.4.7 Local Modes

This section describes the flags for the c_lflag member of the struct termios structure. These flags generally control higher-level aspects of input processing than the input modes flags described in Section 16.4.4 [Input Modes], page 327, such as echoing, signals, and the choice of canonical or noncanonical input.

The c_lflag member itself is an integer, and you change the flags and fields using the operators &, |, and ^. Don't try to specify the entire value for c_lflag—instead, change only specific flags and leave the rest untouched (see Section 16.4.3 [Setting Modes], page 326).

ICANON This bit, if set, enables canonical input processing mode. Otherwise, input is processed in noncanonical mode. See Section 16.3 [Canonical or Not], page 322.

ECHO If this bit is set, echoing of input characters back to the terminal is enabled.

ECHOE If this bit is set, echoing indicates erasure of input with the ERASE character by erasing the last character in the current line from the screen. Otherwise, the character erased is re-echoed to show what has happened (suitable for a printing terminal).

This bit only controls the display behavior; the ICANON bit by itself controls actual recognition of the ERASE character and erasure of input, without which ECHOE is simply irrelevant.

ECHOK

This bit enables special display of the KILL character. There are two ways this can be done. The better way is by erasing on the screen the entire line that has been killed. The worse way is by moving to a new line after echoing the KILL character normally. Some systems do one, some systems do the other, and some let you choose either way.

If this bit is not set, the KILL character echoes just as it would if it were not the KILL character. Then it is up to the user to remember that the KILL character has erased the preceding input; there is no indication of this on the screen.

This bit only controls the display behavior; the ICANON bit by itself controls actual recognition of the KILL character and erasure of input, without which ECHOK is simply irrelevant.

ECHONL If this bit is set and the ICANON bit is also set, then the newline ('\n') character is echoed even if the ECHO bit is not set.

This bit controls whether the INTR, QUIT, and SUSP characters are recognized. The functions associated with these characters are performed if and only if this bit is set. Being in canonical or noncanonical input mode has no affect on the interpretation of these characters.

You should use caution when disabling recognition of these characters. Programs that cannot be interrupted interactively are very user-unfriendly. If you clear this bit, your program should provide some alternate interface that allows the user to interactively send the signals associated with these characters, or to escape from the program.

See Section 16.4.9.3 [Signal Characters], page 338.

This bit is similar to ISIG, but controls implementation-defined special characters. If it is set, it might override the default behavior for the ICANON and ISIG local mode flags, and the IXON and IXOFF input mode flags.

NOFLSH Normally, the INTR, QUIT, and SUSP characters cause input and output queues for the terminal to be cleared. If this bit is set, the queues are not cleared.

TOSTOP If this bit is set and the system supports job control, then SIGTTOU signals are generated by background processes that attempt to write to the terminal. See Section 24.4 [Access to the Terminal], page 497.

The following bits are BSD extensions; the GNU library defines these symbols on any system if you ask for them, but the settings of the bits have no effect except on BSD systems.

On BSD systems, this bit selects between the two alternative ways of displaying the KILL character, when ECHOK is set. If ECHOKE is set, then the KILL character erases the whole screen line; otherwise, the KILL character moves to the next screen line. The setting of ECHOKE has no effect when ECHOK is clear.

ECHOPRT This bit enables display of the ERASE character in a way that is geared to a hardcopy terminal.

ECHOCTL If this bit is set, echo control characters with '^' followed by the corresponding text character. Thus, control-A echoes as '^A'.

ALTWERASE

This bit determines how far the WERASE character should erase. The WERASE character erases back to the beginning of a word; the question is, where do words begin?

If this bit is clear, then the beginning of a word is a nonwhitespace character following a whitespace character. If the bit is set, then the beginning of a word is an alphanumeric character or underscore following a character which is none of those.

FLUSHO This is the bit that toggles when the user types the DISCARD character. While this bit is set, all output is discarded. See Section 16.4.9.5 [Other Special], page 340.

NOKERNINFO

Setting this bit disables handling of the STATUS character. See Section 16.4.9.5 [Other Special], page 340.

PENDIN If this bit is set, it indicates that there is a line of input that needs to be reprinted. Typing the REPRINT character sets this bit; the bit remains set until reprinting is finished. See Section 16.4.9.2 [BSD Editing], page 337.

16.4.8 Line Speed

The terminal line speed tells the computer how fast to read and write data on the terminal.

If the terminal is connected to a real serial line, the terminal speed you specify actually controls the line—if it doesn't match the terminal's own idea of the speed, communication does not work. Real serial ports accept only certain standard speeds. Also, particular hardware may not support even all the standard speeds. Specifying a speed of zero hangs up a dialup connection and turns off modem control signals.

If the terminal is not a real serial line (for example, if it is a network connection), then the line speed won't really affect data transmission speed, but some programs will use it to determine the amount of padding needed. It's best to specify a line speed value that matches the actual speed

of the actual terminal, but you can safely experiment with different values to vary the amount of padding.

There are actually two line speeds for each terminal, one for input and one for output. You can set them independently, but most often terminals use the same speed for both directions.

The speed values are stored in the struct termios structure, but don't try to access them in the struct termios structure directly. Instead, you should use the following functions to read and store them:

speed_t cfgetospeed (const struct termios *termios p)

Function

This function returns the output line speed stored in the structure *termios'p.

speed_t cfgetispeed (const struct termios *termios p)

Function

This function returns the input line speed stored in the structure *termios'p.

int cfsetospeed (struct termios *termios p, speed_t speed)

Function

This function stores *speed* in *termios p as the output speed. The normal return value is 0; a value of -1 indicates an error. If speed is not a speed, cfsetospeed returns -1.

int cfsetispeed (struct termios *termios p, speed_t speed)

Function

This function stores speed in *termios'p as the input speed. The normal return value is 0; a value of -1 indicates an error. If speed is not a speed, cfsetospeed returns -1.

int cfsetspeed (struct termios *termios p, speed_t speed)

Function

This function stores *speed* in *termios'p as both the input and output speeds. The normal return value is 0; a value of -1 indicates an error. If speed is not a speed, cfsetspeed returns -1. This function is an extension in 4.4 BSD.

speed_t

Data Type

The speed_t type is an unsigned integer data type used to represent line speeds.

The functions cfsetospeed and cfsetispeed report errors only for speed values that the system simply cannot handle. If you specify a speed value that is basically acceptable, then those functions will succeed. But they do not check that a particular hardware device can actually support the specified speeds—in fact, they don't know which device you plan to set the speed for. If you use

tcsetattr to set the speed of a particular device to a value that it cannot handle, tcsetattr returns -1.

Portability note: In the GNU library, the functions above accept speeds measured in bits per second as input, and return speed values measured in bits per second. Other libraries require speeds to be indicated by special codes. For POSIX.1 portability, you must use one of the following symbols to represent the speed; their precise numeric values are system-dependent, but each name has a fixed meaning: B110 stands for 110 bps, B300 for 300 bps, and so on. There is no portable way to represent any speed but these, but these are the only speeds that typical serial lines can support.

```
B0 B50 B75 B110 B134 B150 B200
B300 B600 B1200 B1800 B2400 B4800
B9600 B19200 B38400
```

BSD defines two additional speed symbols as aliases: EXTA is an alias for B19200 and EXTB is an alias for B38400. These aliases are obsolete.

16.4.9 Special Characters

In canonical input, the terminal driver recognizes a number of special characters which perform various control functions. These include the ERASE character (usually DEL) for editing input, and other editing characters. The INTR character (normally C-c) for sending a SIGINT signal, and other signal-raising characters, may be available in either canonical or noncanonical input mode. All these characters are described in this section.

The particular characters used are specified in the c_cc member of the struct termios structure. This member is an array; each element specifies the character for a particular role. Each element has a symbolic constant that stands for the index of that element—for example, INTR is

336 The GNU C Library

the index of the element that specifies the INTR character, so storing '=' in termios.c_cc[INTR] specifies '=' as the INTR character.

On some systems, you can disable a particular special character function by specifying the value _POSIX_VDISABLE for that role. This value is unequal to any possible character code. See Section 27.7 [Options for Files], page 555, for more information about how to tell whether the operating system you are using supports _POSIX_VDISABLE.

16.4.9.1 Characters for Input Editing

These special characters are active only in canonical input mode. See Section 16.3 [Canonical or Not], page 322.

int VEOF

This is the subscript for the EOF character in the special control character array. $termios.c_cc[VEOF]$ holds the character itself.

The EOF character is recognized only in canonical input mode. It acts as a line terminator in the same way as a newline character, but if the EOF character is typed at the beginning of a line it causes read to return a byte count of zero, indicating end-of-file. The EOF character itself is discarded.

Usually, the EOF character is C-d.

int VEOL Macro

This is the subscript for the EOL character in the special control character array. termios.c_cc[VEOL] holds the character itself.

The EOL character is recognized only in canonical input mode. It acts as a line terminator, just like a newline character. The EOL character is not discarded; it is read as the last character in the input line.

You don't need to use the EOL character to make RET end a line. Just set the ICRNL flag. In fact, this is the default state of affairs.

int VERASE Macro

This is the subscript for the ERASE character in the special control character array. termios.c_cc[VERASE] holds the character itself.

The ERASE character is recognized only in canonical input mode. When the user types the erase character, the previous character typed is discarded. (If the terminal generates multibyte character sequences, this may cause more than one byte of input to be discarded.) This cannot be used to erase past the beginning of the current line of text. The ERASE character itself is discarded.

Usually, the ERASE character is DEL.

int VKILL Macro

This is the subscript for the KILL character in the special control character array. termios.c_cc[VKILL] holds the character itself.

The KILL character is recognized only in canonical input mode. When the user types the kill character, the entire contents of the current line of input are discarded. The kill character itself is discarded too.

The KILL character is usually C-u.

16.4.9.2 BSD Extensions to Editing Characters

These special characters are active only in canonical input mode. See Section 16.3 [Canonical or Not], page 322. They are BSD extensions; the GNU library defines the symbols on any system if you ask for them, but the characters you specify don't actually do anything except on a BSD system.

int VEOL2 Macro

This is the subscript for the EOL2 character in the special control character array. termios.c_cc[VEOL2] holds the character itself.

The EOL2 character works just like the EOL character (see above), but it can be a different character. Thus, you can specify two characters to terminate an input line, but setting EOL to one of them and EOL2 to the other.

int VWERASE Macro

This is the subscript for the WERASE character in the special control character array. termios.c_cc[VWERASE] holds the character itself.

The WERASE character is recognized only in canonical input mode. It erases an entire word of prior input.

int VREPRINT Macro

This is the subscript for the REPRINT character in the special control character array. termios.c_cc[VREPRINT] holds the character itself.

The REPRINT character is recognized only in canonical input mode. It reprints the current input line.

int VLNEXT Macro

This is the subscript for the LNEXT character in the special control character array. termios.c_cc[VLNEXT] holds the character itself.

The LNEXT character is recognized only when IEXTEN is set. It disables the editing significance of the next character the user types. It is the analogue of the C-q command in Emacs. "LNEXT" stands for "literal next."

The LNEXT character is usually C-v.

16.4.9.3 Characters that Cause Signals

These special characters may be active in either canonical or noncanonical input mode, but only when the ISIG flag is set (see Section 16.4.7 [Local Modes], page 331).

int VINTR Macro

This is the subscript for the INTR character in the special control character array. termios.c_cc[VINTR] holds the character itself.

The INTR (interrupt) character raises a SIGINT signal for all processes in the foreground job associated with the terminal. The INTR character itself is then discarded. See Chapter 21 [Signal Handling], page 403, for more information about signals.

Typically, the INTR character is C-c.

int VQUIT

This is the subscript for the QUIT character in the special control character array. termios.c_cc[VQUIT] holds the character itself.

The QUIT character raises a SIGQUIT signal for all processes in the foreground job associated with the terminal. The QUIT character itself is then discarded. See Chapter 21 [Signal Handling], page 403, for more information about signals.

Typically, the QUIT character is C-\.

int VSUSP Macro

This is the subscript for the SUSP character in the special control character array. termios.c_cc[VSUSP] holds the character itself.

The SUSP (suspend) character is recognized only if the implementation supports job control (see Chapter 24 [Job Control], page 495). It causes a SIGTSTP signal to be sent to all processes in the foreground job associated with the terminal. The SUSP character itself is then discarded. See Chapter 21 [Signal Handling], page 403, for more information about signals.

Typically, the SUSP character is C-z.

Few applications disable the normal interpretation of the SUSP character. If your program does this, it should provide some other mechanism for the user to stop the job. When the user invokes this mechanism, the program should send a SIGTSTP signal to the process group of the process, not just to the process itself. See Section 21.6.2 [Signaling Another Process], page 441.

int VDSUSP Macro

This is the subscript for the DSUSP character in the special control character array. termios.c_cc[VDSUSP] holds the character itself.

The DSUSP (suspend) character is recognized only if the implementation supports job control (see Chapter 24 [Job Control], page 495). It sends a SIGTSTP signal, like the SUSP character, but not right away—only when the program tries to read it as input. Not all systems with job control support DSUSP; only BSD systems.

See Chapter 21 [Signal Handling], page 403, for more information about signals.

Typically, the DSUSP character is C-y.

16.4.9.4 Special Characters for Flow Control

These special characters may be active in either canonical or noncanonical input mode, but their use is controlled by the flags IXON and IXOFF (see Section 16.4.4 [Input Modes], page 327).

int VSTART

This is the subscript for the START character in the special control character array. termios.c_cc[VSTART] holds the character itself.

The START character is used to support the IXON and IXOFF input modes. If IXON is set, receiving a START character resumes suspended output; the START character itself is discarded. If IXOFF is set, the system may also transmit START characters to the terminal.

The usual value for the START character is C-q. You may not be able to change this value—the hardware may insist on using C-q regardless of what you specify.

int VSTOP Macro

This is the subscript for the STOP character in the special control character array. termios.c_cc[VSTOP] holds the character itself.

The STOP character is used to support the IXON and IXOFF input modes. If IXON is set, receiving a STOP character causes output to be suspended; the STOP character itself is discarded. If IXOFF is set, the system may also transmit STOP characters to the terminal, to prevent the input queue from overflowing.

The usual value for the STOP character is C-s. You may not be able to change this value—the hardware may insist on using C-s regardless of what you specify.

16.4.9.5 Other Special Characters

Here are two additional special characters that are meaningful on BSD systems.

int VDISCARD Macro

This is the subscript for the DISCARD character in the special control character array. termios.c_cc[VDISCARD] holds the character itself.

The DISCARD character is recognized only when IEXTEN is set. Its effect is to toggle the discard-output flag. When this flag is set, all program output is discarded. Setting the flag also discards all output currently in the output buffer.

int VSTATUS Macro

This is the subscript for the STATUS character in the special control character array. termios.c_cc[VSTATUS] holds the character itself.

The STATUS character's effect is to print out a status message about how the current process is running.

The STATUS character is recognized only when canonical mode. This is a peculiar design decision, since the STATUS character's meaning has nothing to do with input, but that's the way it was done.

16.4.10 Noncanonical Input

In noncanonical input mode, the special editing characters such as ERASE and KILL are ignored. The system facilities for the user to edit input are disabled in noncanonical mode, so that all input characters (unless they are special for signal or flow-control purposes) are passed to the application program exactly as typed. It is up to the application program to give the user ways to edit the input, if appropriate.

Noncanonical mode offers special parameters called MIN and TIME for controlling whether and how long to wait for input to be available. You can even use them to avoid ever waiting—to return immediately with whatever input is available, or with no input.

The MIN and TIME are stored in elements of the c_cc array, which is a member of the struct termios structure. Each element of this array has a particular role, and each element has a symbolic constant that stands for the index of that element. VMIN and VMAX are the names for the indices in the array of the MIN and TIME slots.

int VMIN Macro

This is the subscript for the MIN slot in the c_cc array. Thus, termios.c_cc[VMIN] is the value itself.

The MIN slot is only meaningful in noncanonical input mode; it specifies the minimum number of bytes that must be available in the input queue in order for read to return.

int VTIME Macro

This is the subscript for the TIME slot in the c_cc array. Thus, termios.c_cc[VTIME] is the value itself.

The TIME slot is only meaningful in noncanonical input mode; it specifies how long to wait for input before returning, in units of 0.1 seconds.

The MIN and TIME values interact to determine the criterion for when read should return; their precise meanings depend on which of them are nonzero. There are four possible cases:

• Both MIN and TIME are zero.

342

In this case, read always returns immediately with as many characters as are available in the queue, up to the number requested. If no input is immediately available, read returns a value of zero.

• MIN is zero but TIME has a nonzero value.

In this case, read waits for time TIME for input to become available; the availability of a single byte is enough to satisfy the read request and cause read to return. When it returns, it returns as many characters as are available, up to the number requested. If no input is available before the timer expires, read returns a value of zero.

• TIME is zero but MIN has a nonzero value.

In this case, read waits until at least MIN bytes are available in the queue. At that time, read returns as many characters as are available, up to the number requested. read can return more than MIN characters if more than MIN happen to be in the queue.

• Both TIME and MIN are nonzero.

In this case, TIME specifies how long to wait after each input character to see if more input arrives. read keeps waiting until either MIN bytes have arrived, or TIME elapses with no further input.

read can return no input if TIME elapses before the first input character arrives. read can return more than MIN characters if more than MIN happen to be in the queue.

What happens if MIN is 50 and you ask to read just 10 bytes? Normally, read waits until there are 50 bytes in the buffer (or, more generally, the wait condition described above is satisfied), and then reads 10 of them, leaving the other 40 buffered in the operating system for a subsequent call to read.

Portability note: On some systems, the MIN and TIME slots are actually the same as the EOF and EOL slots. This causes no serious problem because the MIN and TIME slots are used only in noncanonical input and the EOF and EOL slots are used only in canonical input, but it isn't very clean. The GNU library allocates separate slots for these uses.

16.5 Line Control Functions

These functions perform miscellaneous control actions on terminal devices. As regards terminal access, they are treated like doing output: if any of these functions is used by a background process on its controlling terminal, normally all processes in the process group are sent a SIGTTOU signal. The exception is if the calling process itself is ignoring or blocking SIGTTOU signals, in which case the operation is performed and no signal is sent. See Chapter 24 [Job Control], page 495.

int tcsendbreak (int filedes, int duration)

Function

This function generates a break condition by transmitting a stream of zero bits on the terminal associated with the file descriptor *filedes*. The duration of the break is controlled by the *duration* argument. If zero, the duration is between 0.25 and 0.5 seconds. The meaning of a nonzero value depends on the operating system.

This function does nothing if the terminal is not an asynchronous serial data port.

The return value is normally zero. In the event of an error, a value of -1 is returned. The following error conditions are defined for this function:

EBADF The filedes is not a valid file descriptor.

ENOTTY The *filedes* is not associated with a terminal device.

int tcdrain (int filedes)

Function

The tcdrain function waits until all queued output to the terminal filedes has been transmitted.

The return value is normally zero. In the event of an error, a value of -1 is returned. The following error conditions are defined for this function:

EBADF The filedes is not a valid file descriptor.

ENOTTY The filedes is not associated with a terminal device.

EINTR The operation was interrupted by delivery of a signal. See Section 21.5

[Interrupted Primitives], page 438.

int tcflush (int filedes, int queue)

Function

The tcflush function is used to clear the input and/or output queues associated with the terminal file filedes. The queue argument specifies which queue(s) to clear, and can be one of the following values:

TCIFLUSH

Clear any input data received, but not yet read.

TCOFLUSH

Clear any output data written, but not yet transmitted.

TCIOFLUSH

Clear both queued input and output.

The return value is normally zero. In the event of an error, a value of -1 is returned. The following error conditions are defined for this function:

EBADF The filedes is not a valid file descriptor.

ENOTTY The *filedes* is not associated with a terminal device.

EINVAL A bad value was supplied as the queue argument.

It is unfortunate that this function is named tcflush, because the term "flush" is normally used for quite another operation—waiting until all output is transmitted—and using it for discarding input or output would be confusing. Unfortunately, the name tcflush comes from POSIX and we cannot change it.

int tcflow (int filedes, int action)

Function

The tcflow function is used to perform operations relating to XON/XOFF flow control on the terminal file specified by filedes.

The action argument specifies what operation to perform, and can be one of the following values:

TC00FF	Suspend transmission of output.
TCOON	Restart transmission of output.
TCIOFF	Transmit a STOP character.
TCION	Transmit a START character.

For more information about the STOP and START characters, see Section 16.4.9 [Special Characters], page 335.

The return value is normally zero. In the event of an error, a value of -1 is returned. The following error conditions are defined for this function:

EBADF The filedes is not a valid file descriptor.

ENOTTY The filedes is not associated with a terminal device.

EINVAL A bad value was supplied as the action argument.

16.6 Noncanonical Mode Example

Here is an example program that shows how you can set up a terminal device to read single characters in noncanonical input mode, without echo.

```
#include <unistd.h>
#include <stdio.h>
#include <stdlib.h>
#include <termios.h>

/* Use this variable to remember original terminal attributes. */
struct termios saved_attributes;
void
```

```
reset_input_mode (void)
  tcsetattr (STDIN_FILENO, TCSANOW, &saved_attributes);
}
void
set_input_mode (void)
  struct termios tattr;
  char *name;
  /* Make sure stdin is a terminal. */
  if (!isatty (STDIN_FILENO))
    {
      fprintf (stderr, "Not a terminal.\n");
      exit (EXIT_FAILURE);
    }
  /* Save the terminal attributes so we can restore them later. */
  tcgetattr (STDIN_FILENO, &saved_attributes);
  atexit (reset_input_mode);
  /* Set the funny terminal modes. */
  tcgetattr (STDIN_FILENO, &tattr);
  tattr.c_lflag &= ~(ICANON|ECHO); /* Clear ICANON and ECHO. */
  tattr.c_cc[VMIN] = 1;
  tattr.c_cc[VTIME] = 0;
  tcsetattr (STDIN_FILENO, TCSAFLUSH, &tattr);
}
int
main (void)
{
  char c;
  set_input_mode ();
  while (1)
      read (STDIN_FILENO, &c, 1);
      if (c == '\004') /* C-d */
break;
      else
putchar (c);
  return EXIT_SUCCESS;
}
```

This program is careful to restore the original terminal modes before exiting or terminating with a signal. It uses the atexit function (see Section 22.3.3 [Cleanups on Exit], page 478) to make sure this is done by exit.

The signals handled in the example are the ones that typically occur due to actions of the user. It might be desirable to handle other signals such as SIGSEGV that can result from bugs in the program.

The shell is supposed to take care of resetting the terminal modes when a process is stopped or continued; see Chapter 24 [Job Control], page 495. But some existing shells do not actually do this, so you may wish to establish handlers for job control signals that reset terminal modes. The above example does so.

17 Mathematics

This chapter contains information about functions for performing mathematical computations, such as trigonometric functions. Most of these functions have prototypes declared in the header file 'math.h'.

All of the functions that operate on floating-point numbers accept arguments and return results of type double. In the future, there may be additional functions that operate on float and long double values. For example, cosf and cosl would be versions of the cos function that operate on float and long double arguments, respectively. In the meantime, you should avoid using these names yourself. See Section 1.3.3 [Reserved Names], page 7.

17.1 Domain and Range Errors

Many of the functions listed in this chapter are defined mathematically over a domain that is only a subset of real numbers. For example, the acos function is defined over the domain between -1 and 1. If you pass an argument to one of these functions that is outside the domain over which it is defined, the function sets errno to EDOM to indicate a domain error. On machines that support IEEE floating point, functions reporting error EDOM also return a NaN.

Some of these functions are defined mathematically to result in a complex value over parts of their domains. The most familiar example of this is taking the square root of a negative number. The functions in this chapter take only real arguments and return only real values; therefore, if the value ought to be nonreal, this is treated as a domain error.

A related problem is that the mathematical result of a function may not be representable as a floating point number. If magnitude of the correct result is too large to be represented, the function sets errno to ERANGE to indicate a range error, and returns a particular very large value (named by the macro HUGE_VAL) or its negation (- HUGE_VAL).

If the magnitude of the result is too small, a value of zero is returned instead. In this case, errno might or might not be set to ERANGE.

The only completely reliable way to check for domain and range errors is to set **errno** to 0 before you call the mathematical function and test **errno** afterward. As a consequence of this use of **errno**, use of the mathematical functions is not reentrant if you check for errors.

350 The GNU C Library

None of the mathematical functions ever generates signals as a result of domain or range errors. In particular, this means that you won't see SIGFPE signals generated within these functions. (See Chapter 21 [Signal Handling], page 403, for more information about signals.)

double HUGE_VAL Macro

An expression representing a particular very large number. On machines that use IEEE floating point format, the value is "infinity". On other machines, it's typically the largest positive number that can be represented.

The value of this macro is used as the return value from various mathematical functions in overflow situations.

For more information about floating-point representations and limits, see Section A.5.3.2 [Floating Point Parameters], page 578. In particular, the macro DBL_MAX might be more appropriate than HUGE_VAL for many uses other than testing for an error in a mathematical function.

17.2 Trigonometric Functions

These are the familiar sin, cos, and tan functions. The arguments to all of these functions are in units of radians; recall that pi radians equals 180 degrees.

The math library doesn't define a symbolic constant for pi, but you can define your own if you need one:

#define PI 3.14159265358979323846264338327

You can also compute the value of pi with the expression acos (-1.0).

double \sin (double x)

Function

This function returns the sine of x, where x is given in radians. The return value is in the range -1 to 1.

double \cos (double x)

Function

This function returns the cosine of x, where x is given in radians. The return value is in the range -1 to 1.

double tan (double x)

Function

This function returns the tangent of x, where x is given in radians.

The following errno error conditions are defined for this function:

F.R.ANGE

Mathematically, the tangent function has singularities at odd multiples of pi/2. If the argument x is too close to one of these singularities, tan sets errno to ERANGE and returns either positive or negative HUGE_VAL.

17.3 Inverse Trigonometric Functions

These are the usual arc sine, arc cosine and arc tangent functions, which are the inverses of the sine, cosine and tangent functions, respectively.

double as in (double x)

Function

This function computes the arc sine of x—that is, the value whose sine is x. The value is in units of radians. Mathematically, there are infinitely many such values; the one actually returned is the one between -pi/2 and pi/2 (inclusive).

asin fails, and sets errno to EDOM, if x is out of range. The arc sine function is defined mathematically only over the domain -1 to 1.

double acos (double x)

Function

This function computes the arc cosine of x—that is, the value whose cosine is x. The value is in units of radians. Mathematically, there are infinitely many such values; the one actually returned is the one between 0 and pi (inclusive).

acos fails, and sets errno to EDOM, if x is out of range. The arc cosine function is defined mathematically only over the domain -1 to 1.

double at an (double x)

Function

This function computes the arc tangent of x—that is, the value whose tangent is x. The value is in units of radians. Mathematically, there are infinitely many such values; the one actually returned is the one between -pi/2 and pi/2 (inclusive).

double at an 2 (double y, double x)

Function

This is the two argument arc tangent function. It is similar to computing the arc tangent of y/x, except that the signs of both arguments are used to determine the quadrant of the result, and x is permitted to be zero. The return value is given in radians and is in the range -pi to pi, inclusive.

If x and y are coordinates of a point in the plane, atan2 returns the signed angle between the line from the origin to that point and the x-axis. Thus, atan2 is useful for converting Cartesian coordinates to polar coordinates. (To compute the radial coordinate, use hypot; see Section 17.4 [Exponents and Logarithms], page 352.)

The function atan2 sets errno to EDOM if both x and y are zero; the return value is not defined in this case.

17.4 Exponentiation and Logarithms

double exp (double x)

Function

The exp function returns the value of e (the base of natural logarithms) raised to power x.

The function fails, and sets errno to ERANGE, if the magnitude of the result is too large to be representable.

double \log (double x)

Function

This function returns the natural logarithm of x. exp(log(x)) equals x, exactly in mathematics and approximately in C.

The following errno error conditions are defined for this function:

EDOM The argument x is negative. The log function is defined mathematically

to return a real result only on positive arguments.

ERANGE The argument is zero. The log of zero is not defined.

double log10 (double x)

Function

This function returns the base-10 logarithm of x. Except for the different base, it is similar to the log function. In fact, log10 (x) equals log (x) / log (10).

double **pow** (double base, double power)

Function

This is a general exponentiation function, returning base raised to power.

The following errno error conditions are defined for this function:

EDOM The argument base is negative and power is not an integral value. Math-

ematically, the result would be a complex number in this case.

ERANGE An underflow or overflow condition was detected in the result.

double \mathbf{sqrt} (double x)

Function

This function returns the nonnegative square root of x.

The sqrt function fails, and sets errno to EDOM, if x is negative. Mathematically, the square root would be a complex number.

double \mathbf{cbrt} (double x)

Function

This function returns the cube root of x. This function cannot fail; every representable real value has a representable real cube root.

double hypot (double x, double y)

Function

The hypot function returns sqrt (x*x + y*y). (This is the length of the hypotenuse of a right triangle with sides of length x and y, or the distance of the point (x, y) from the origin.) See also the function cabs in Section 18.3 [Absolute Value], page 360.

double expm1 (double x)

Function

This function returns a value equivalent to $\exp(x) - 1$. It is computed in a way that is accurate even if the value of x is near zero—a case where $\exp(x) - 1$ would be inaccurate due to subtraction of two numbers that are nearly equal.

double log1p (double x)

Function

This function returns a value equivalent to log (1 + x). It is computed in a way that is accurate even if the value of x is near zero.

17.5 Hyperbolic Functions

The functions in this section are related to the exponential functions; see Section 17.4 [Exponents and Logarithms], page 352.

double sinh (double x)

Function

The sinh function returns the hyperbolic sine of x, defined mathematically as $\exp(x) - \exp(-x) / 2$. The function fails, and sets errno to ERANGE, if the value of x is too large; that is, if overflow occurs.

double cosh (double x)

Function

The cosh function returns the hyperbolic cosine of x, defined mathematically as $\exp(x) + \exp(-x) / 2$. The function fails, and sets errno to ERANGE, if the value of x is too large; that is, if overflow occurs.

double tanh (double x)

Function

This function returns the hyperbolic tangent of x, whose mathematical definition is $\sinh(x) / \cosh(x)$.

double asinh (double x)

Function

This function returns the inverse hyperbolic sine of x—the value whose hyperbolic sine is x.

double a cosh (double x)

Function

This function returns the inverse hyperbolic cosine of x—the value whose hyperbolic cosine is x. If x is less than 1, acosh returns HUGE_VAL.

double atanh (double x)

Function

This function returns the inverse hyperbolic tangent of x—the value whose hyperbolic tangent is x. If the absolute value of x is greater than or equal to 1, atanh returns $HUGE_VAL$.

17.6 Pseudo-Random Numbers

This section describes the GNU facilities for generating a series of pseudo-random numbers. The numbers generated are not truly random; typically, they form a sequence that repeats periodically,

with a period so large that you can ignore it for ordinary purposes. The random number generator works by remembering at all times a *seed* value which it uses to compute the next random number and also to compute a new seed.

Although the generated numbers look unpredictable within one run of a program, the sequence of numbers is exactly the same from one run to the next. This is because the initial seed is always the same. This is convenient when you are debugging a program, but it is unhelpful if you want the program to behave unpredictably. If you want truly random numbers, not just pseudo-random, specify a seed based on the current time.

You can get repeatable sequences of numbers on a particular machine type by specifying the same initial seed value for the random number generator. There is no standard meaning for a particular seed value; the same seed, used in different C libraries or on different CPU types, will give you different random numbers.

The GNU library supports the standard ANSI C random number functions plus another set derived from BSD. We recommend you use the standard ones, rand and srand.

17.6.1 ANSI C Random Number Functions

This section describes the random number functions that are part of the ANSI C standard.

To use these facilities, you should include the header file 'stdlib.h' in your program.

int RAND_MAX Macro

The value of this macro is an integer constant expression that represents the maximum possible value returned by the rand function. In the GNU library, it is 037777777, which is the largest signed integer representable in 32 bits. In other libraries, it may be as low as 32767.

int rand () Function

The rand function returns the next pseudo-random number in the series. The value is in the range from 0 to RAND_MAX.

void **srand** (unsigned int seed)

Function

This function establishes *seed* as the seed for a new series of pseudo-random numbers. If you call rand before a seed has been established with **srand**, it uses the value 1 as a default seed.

To produce truly random numbers (not just pseudo-random), do srand (time (0)).

17.6.2 BSD Random Number Functions

This section describes a set of random number generation functions that are derived from BSD. There is no advantage to using these functions with the GNU C library; we support them for BSD compatibility only.

The prototypes for these functions are in 'stdlib.h'.

long int random ()

Function

This function returns the next pseudo-random number in the sequence. The range of values returned is from 0 to RAND_MAX.

void srandom (unsigned int seed)

Function

The **srandom** function sets the seed for the current random number state based on the integer *seed*. If you supply a *seed* value of 1, this will cause **random** to reproduce the default set of random numbers.

To produce truly random numbers (not just pseudo-random), do srandom (time (0)).

void * initstate (unsigned int seed, void *state, size_t size)

Function

The initstate function is used to initialize the random number generator state. The argument *state* is an array of *size* bytes, used to hold the state information. The size must be at least 8 bytes, and optimal sizes are 8, 16, 32, 64, 128, and 256. The bigger the *state* array, the better.

The return value is the previous value of the state information array. You can use this value later as an argument to **setstate** to restore that state.

void * setstate (void *state)

Function

The setstate function restores the random number state information state. The argument must have been the result of a previous call to initstate or setstate.

The return value is the previous value of the state information array. You can use thise value later as an argument to **setstate** to restore that state.

358

18 Low-Level Arithmetic Functions

This chapter contains information about functions for doing basic arithmetic operations, such as splitting a float into its integer and fractional parts. These functions are declared in the header file 'math.h'.

18.1 "Not a Number" Values

The IEEE floating point format used by most modern computers supports values that are "not a number". These values are called *NaNs*. "Not a number" values result from certain operations which have no meaningful numeric result, such as zero divided by zero or infinity divided by infinity.

One noteworthy property of NaNs is that they are not equal to themselves. Thus, $\mathbf{x} == \mathbf{x}$ can be 0 if the value of \mathbf{x} is a NaN. You can use this to test whether a value is a NaN or not: if it is not equal to itself, then it is a NaN. But the recommended way to test for a NaN is with the **isnan** function (see Section 18.2 [Predicates on Floats], page 359).

Almost any arithmetic operation in which one argument is a NaN returns a NaN.

double NAN Macro

An expression representing a value which is "not a number". This macro is a GNU extension, available only on machines that support "not a number" values—that is to say, on all machines that support IEEE floating point.

You can use '#ifdef NAN' to test whether the machine supports NaNs. (Of course, you must arrange for GNU extensions to be visible, such as by defining _GNU_SOURCE, and then you must include 'math.h'.)

18.2 Predicates on Floats

This section describes some miscellaneous test functions on doubles. Prototypes for these functions appear in 'math.h'. These are BSD functions, and thus are available if you define _BSD_SOURCE or _GNU_SOURCE.

The GNU C Library

int isinf (double x)

360

Function

This function returns -1 if x represents negative infinity, 1 if x represents positive infinity, and 0 otherwise.

int isnan (double x)

Function

This function returns a nonzero value if x is a "not a number" value, and zero otherwise. (You can just as well use x != x to get the same result).

int finite (double x)

Function

This function returns a nonzero value if x is finite or a "not a number" value, and zero otherwise.

double infnan (int error)

Function

This function is provided for compatibility with BSD. The other mathematical functions use infnan to decide what to return on occasion of an error. Its argument is an error code, EDOM or ERANGE; infnan returns a suitable value to indicate this with. -ERANGE is also acceptable as an argument, and corresponds to -HUGE_VAL as a value.

In the BSD library, on certain machines, infnan raises a fatal signal in all cases. The GNU library does not do likewise, because that does not fit the ANSI C specification.

Portability Note: The functions listed in this section are BSD extensions.

18.3 Absolute Value

These functions are provided for obtaining the absolute value (or magnitude) of a number. The absolute value of a real number x is x is positive, -x if x is negative. For a complex number z, whose real part is x and whose imaginary part is y, the absolute value is sqrt (x*x + y*y).

Prototypes for abs and labs are in 'stdlib.h'; fabs and cabs are declared in 'math.h'.

int abs (int number)

Function

This function returns the absolute value of number.

Most computers use a two's complement integer representation, in which the absolute value of INT_MIN (the smallest possible int) cannot be represented; thus, abs (INT_MIN) is not defined.

long int labs (long int number)

Function

This is similar to abs, except that both the argument and result are of type long int rather than int.

double fabs (double number)

Function

This function returns the absolute value of the floating-point number number.

double cabs (struct { double real, imag; } z)

Function

The cabs function returns the absolute value of the complex number z, whose real part is z.real and whose imaginary part is z.imag. (See also the function hypot in Section 17.4 [Exponents and Logarithms], page 352.) The value is:

sqrt(z.real*z.real+z.imag*z.imag)

18.4 Normalization Functions

The functions described in this section are primarily provided as a way to efficiently perform certain low-level manipulations on floating point numbers that are represented internally using a binary radix; see Section A.5.3.1 [Floating Point Concepts], page 576. These functions are required to have equivalent behavior even if the representation does not use a radix of 2, but of course they are unlikely to be particularly efficient in those cases.

All these functions are declared in 'math.h'.

double frexp (double value, int *exponent)

Function

The frexp function is used to split the number value into a normalized fraction and an exponent.

If the argument value is not zero, the return value is value times a power of two, and is always in the range 1/2 (inclusive) to 1 (exclusive). The corresponding exponent is stored in *exponent; the return value multiplied by 2 raised to this exponent equals the original number value.

For example, frexp (12.8, &exponent) returns 0.8 and stores 4 in exponent.

If value is zero, then the return value is zero and zero is stored in *exponent.

double ldexp (double value, int exponent)

Function

This function returns the result of multiplying the floating-point number value by 2 raised to the power exponent. (It can be used to reassemble floating-point numbers that were taken apart by frexp.)

For example, 1dexp (0.8, 4) returns 12.8.

The following functions which come from BSD provide facilities equivalent to those of ldexp and frexp:

double scalb (double value, int exponent)

Function

The scalb function is the BSD name for ldexp.

double logb (double x)

Function

This BSD function returns the integer part of the base-2 logarithm of x, an integer value represented in type double. This is the highest integer power of 2 contained in x. The sign of x is ignored. For example, logb (3.5) is 1.0 and logb (4.0) is 2.0.

When 2 raised to this power is divided into x, it gives a quotient between 1 (inclusive) and 2 (exclusive).

If x is zero, the value is minus infinity (if the machine supports such a value), or else a very small number. If x is infinity, the value is infinity.

The value returned by logb is one less than the value that frexp would store into *exponent.

double copysign (double value, double sign)

Function

The copysign function returns a value whose absolute value is the same as that of value, and whose sign matches that of sign. This is a BSD function.

18.5 Rounding and Remainder Functions

The functions listed here perform operations such as rounding, truncation, and remainder in division of floating point numbers. Some of these functions convert floating point numbers to integer values. They are all declared in 'math.h'.

You can also convert floating-point numbers to integers simply by casting them to int. This discards the fractional part, effectively rounding towards zero. However, this only works if the result can actually be represented as an int—for very large numbers, this is impossible. The functions listed here return the result as a double instead to get around this problem.

double ceil (double x)

Function

The ceil function rounds x upwards to the nearest integer, returning that value as a double. Thus, ceil (1.5) is 2.0.

double floor (double x)

Function

The ceil function rounds x downwards to the nearest integer, returning that value as a double. Thus, floor (1.5) is 1.0 and floor (-1.5) is -2.0.

double rint (double x)

Function

This function rounds x to an integer value according to the current rounding mode. See Section A.5.3.2 [Floating Point Parameters], page 578, for information about the various rounding modes. The default rounding mode is to round to the nearest integer; some machines support other modes, but round-to-nearest is always used unless you explicit select another.

double modf (double value, double *integer part)

Function

This function breaks the argument *value* into an integer part and a fractional part (between -1 and 1, exclusive). Their sum equals *value*. Each of the parts has the same sign as *value*, so the rounding of the integer part is towards zero.

modf stores the integer part in *integer part, and returns the fractional part. For example, modf (2.5, &intpart) returns 0.5 and stores 2.0 into intpart.

double fmod (double numerator, double denominator)

Function

This function computes the remainder of dividing numerator by denominator. Specifically, the return value is numerator – n * denominator, where n is the quotient

The GNU C Library

of numerator divided by denominator, rounded towards zero to an integer. Thus, fmod (6.5, 2.3) returns 1.9, which is 6.5 minus 4.6.

The result has the same sign as the *numerator* and has magnitude less than the magnitude of the *denominator*.

If denominator is zero, fmod fails and sets errno to EDOM.

double drem (double numerator, double denominator)

Function

The function drem is like fmod except that it rounds the internal quotient n to the nearest integer instead of towards zero to an integer. For example, drem (6.5, 2.3) returns -0.4, which is 6.5 minus 6.9.

The absolute value of the result is less than or equal to half the absolute value of the denominator. The difference between fmod (numerator, denominator) and drem (numerator, denominator) is always either denominator, minus denominator, or zero.

If denominator is zero, drem fails and sets errno to EDOM.

18.6 Integer Division

364

This section describes functions for performing integer division. These functions are redundant in the GNU C library, since in GNU C the '/' operator always rounds towards zero. But in other C implementations, '/' may round differently with negative arguments. div and ldiv are useful because they specify how to round the quotient: towards zero. The remainder has the same sign as the numerator.

These functions are specified to return a result r such that r.quot*denominator + r.rem equals numerator.

To use these facilities, you should include the header file 'stdlib.h' in your program.

div_t

Data Type

This is a structure type used to hold the result returned by the div function. It has the following members:

int quot The quotient from the division.

int rem The remainder from the division.

div_t div (int numerator, int denominator)

Function

This function div computes the quotient and remainder from the division of numerator by denominator, returning the result in a structure of type div_t.

If the result cannot be represented (as in a division by zero), the behavior is undefined.

Here is an example, albeit not a very useful one.

```
div_t result;
result = div (20, -6);
```

Now result.quot is -3 and result.rem is 2.

ldiv_t Data Type

This is a structure type used to hold the result returned by the ldiv function. It has the following members:

long int quot

The quotient from the division.

long int rem

The remainder from the division.

(This is identical to div_t except that the components are of type long int rather than int.)

ldiv_t ldiv (long int numerator, long int denominator)

Function

The ldiv function is similar to div, except that the arguments are of type long int and the result is returned as a structure of type ldiv.

18.7 Parsing of Numbers

This section describes functions for "reading" integer and floating-point numbers from a string. It may be more convenient in some cases to use **sscanf** or one of the related functions; see Section 11.11 [Formatted Input], page 173. But often you can make a program more robust by finding the tokens in the string by hand, then converting the numbers one by one.

18.7.1 Parsing of Integers

These functions are declared in 'stdlib.h'.

long int strtol (const char *string, char **tailptr, int base) Function
The strtol ("string-to-long") function converts the initial part of string to a signed integer, which is returned as a value of type long int.

This function attempts to decompose string as follows:

- A (possibly empty) sequence of whitespace characters. Which characters are whitespace is determined by the isspace function (see Section 4.1 [Classification of Characters], page 61). These are discarded.
- An optional plus or minus sign ('+' or '-').
- A nonempty sequence of digits in the radix specified by base.
 - If base is zero, decimal radix is assumed unless the series of digits begins with '0' (specifying octal radix), or '0x' or '0x' (specifying hexadecimal radix); in other words, the same syntax used for integer constants in C.
 - Otherwise base must have a value between 2 and 35. If base is 16, the digits may optionally be preceded by 0x or 0X.
- Any remaining characters in the string. If *tailptr* is not a null pointer, **strtol** stores a pointer to this tail in **tailptr*.

If the string is empty, contains only whitespace, or does not contain an initial substring that has the expected syntax for an integer in the specified *base*, no conversion is performed. In this case, **strtol** returns a value of zero and the value stored in *tailptr is the value of string.

In a locale other than the standard "C" locale, this function may recognize additional implementation-dependent syntax.

If the string has valid syntax for an integer but the value is not representable because of overflow, strtol returns either LONG_MAX or LONG_MIN (see Section A.5.2 [Range of Type], page 574), as appropriate for the sign of the value. It also sets errno to ERANGE to indicate there was overflow.

There is an example at the end of this section.

```
unsigned long int strtoul (const char *string, char **tailptr, int base)
```

The strtoul ("string-to-unsigned-long") function is like strtol except that it returns its value with type unsigned long int. The value returned in case of overflow is ULONG_MAX (see Section A.5.2 [Range of Type], page 574).

```
long int atol (const char *string)
```

Function

This function is similar to the **strtol** function with a base argument of 10, except that it need not detect overflow errors. The **atol** function is provided mostly for compatibility with existing code; using **strtol** is more robust.

```
int atoi (const char *string)
```

Function

This function is like atol, except that it returns an int value rather than long int. The atoi function is also considered obsolete; use strtol instead.

Here is a function which parses a string as a sequence of integers and returns the sum of them:

```
sum_ints_from_string (char *string)
{
  int sum = 0;

while (1) {
    char *tail;
    int next;

  /* Skip whitespace by hand, to detect the end. */
    while (isspace (*string)) string++;
    if (*string == 0)
        break;
```

```
/* There is more nonwhitespace, */
/* so it ought to be another number. */
errno = 0;
/* Parse it. */
next = strtol (string, &tail, 0);
/* Add it in, if not overflow. */
if (errno)
    printf ("Overflow\n");
else
    sum += next;
/* Advance past it. */
string = tail;
}
return sum;
}
```

18.7.2 Parsing of Floats

These functions are declared in 'stdlib.h'.

```
double strtod (const char *string, char **tailptr)
```

Function

The strtod ("string-to-double") function converts the initial part of string to a floating-point number, which is returned as a value of type double.

This function attempts to decompose string as follows:

- A (possibly empty) sequence of whitespace characters. Which characters are whitespace is determined by the isspace function (see Section 4.1 [Classification of Characters], page 61). These are discarded.
- An optional plus or minus sign ('+' or '-').
- A nonempty sequence of digits optionally containing a decimal-point character—normally '.', but it depends on the locale (see Section 7.6 [Numeric Formatting], page 102).
- An optional exponent part, consisting of a character 'e' or 'E', an optional sign, and a sequence of digits.
- Any remaining characters in the string. If *tailptr* is not a null pointer, a pointer to this tail of the string is stored in **tailptr*.

If the string is empty, contains only whitespace, or does not contain an initial substring that has the expected syntax for a floating-point number, no conversion is performed. In this case, **strtod** returns a value of zero and the value returned in *tailptr is the value of string.

In a locale other than the standard "C" locale, this function may recognize additional locale-dependent syntax.

If the string has valid syntax for a floating-point number but the value is not representable because of overflow, strtod returns either positive or negative HUGE_VAL (see Chapter 17 [Mathematics], page 349), depending on the sign of the value. Similarly, if the value is not representable because of underflow, strtod returns zero. It also sets errno to ERANGE if there was overflow or underflow.

double atof (const char *string)

Function

This function is similar to the **strtod** function, except that it need not detect overflow and underflow errors. The **atof** function is provided mostly for compatibility with existing code; using **strtod** is more robust.

19 Date and Time

This chapter describes functions for manipulating dates and times, including functions for determining what the current time is and conversion between different time representations.

The time functions fall into three main categories:

- Functions for measuring elapsed CPU time are discussed in Section 19.1 [Processor Time], page 371.
- Functions for measuring absolute clock or calendar time are discussed in Section 19.2 [Calendar Time], page 374.
- Functions for setting alarms and timers are discussed in Section 19.3 [Setting an Alarm], page 387.

19.1 Processor Time

If you're trying to optimize your program or measure its efficiency, it's very useful to be able to know how much processor time or CPU time it has used at any given point. Processor time is different from actual wall clock time because it doesn't include any time spent waiting for I/O or when some other process is running. Processor time is represented by the data type clock_t, and is given as a number of clock ticks relative to an arbitrary base time marking the beginning of a single program invocation.

19.1.1 Basic CPU Time Inquiry

To get the elapsed CPU time used by a process, you can use the clock function. This facility is declared in the header file 'time.h'.

In typical usage, you call the clock function at the beginning and end of the interval you want to time, subtract the values, and then divide by CLOCKS_PER_SEC (the number of clock ticks per second), like this:

```
#include <time.h>
clock_t start, end;
double elapsed;
start = clock();
... /* Do the work. */
end = clock();
elapsed = ((double) (end - start)) / CLOCKS_PER_SEC;
```

Different computers and operating systems vary wildly in how they keep track of processor time. It's common for the internal processor clock to have a resolution somewhere between hundredths and millionths of a second.

In the GNU system, clock_t is equivalent to long int and CLOCKS_PER_SEC is an integer value. But in other systems, both clock_t and the type of the macro CLOCKS_PER_SEC can be either integer or floating-point types. Casting processor time values to double, as in the example above, makes sure that operations such as arithmetic and printing work properly and consistently no matter what the underlying representation is.

int CLOCKS_PER_SEC

Macro

The value of this macro is the number of clock ticks per second measured by the clock function.

int CLK_TCK Macro

This is an obsolete name for CLOCKS_PER_SEC.

clock_t Data Type

This is the type of the value returned by the clock function. Values of type clock_t are in units of clock ticks.

clock_t clock (void)

Function

This function returns the elapsed processor time. The base time is arbitrary but doesn't change within a single process. If the processor time is not available or cannot be represented, clock returns the value (clock_t)(-1).

19.1.2 Detailed Elapsed CPU Time Inquiry

The times function returns more detailed information about elapsed processor time in a struct tms object. You should include the header file 'sys/times.h' to use this facility.

struct tms Data Type

The tms structure is used to return information about process times. It contains at least the following members:

clock_t tms_utime

This is the CPU time used in executing the instructions of the calling process.

clock_t tms_stime

This is the CPU time used by the system on behalf of the calling process.

clock_t tms_cutime

This is the sum of the tms_utime values and the tms_cutime values of all terminated child processes of the calling process, whose status has been reported to the parent process by wait or waitpid; see Section 23.6 [Process Completion], page 488. In other words, it represents the total CPU time used in executing the instructions of all the terminated child processes of the calling process.

clock_t tms_cstime

This is similar to tms_cutime, but represents the total CPU time used by the system on behalf of all the terminated child processes of the calling process.

All of the times are given in clock ticks. These are absolute values; in a newly created process, they are all zero. See Section 23.4 [Creating a Process], page 483.

clock_t times (struct tms *buffer)

Function

The times function stores the processor time information for the calling process in buffer.

The return value is the same as the value of clock(): the elapsed real time relative to an arbitrary base. The base is a constant within a particular process, and typically represents the time since system start-up. A value of (clock_t)(-1) is returned to indicate failure.

Portability Note: The clock function described in Section 19.1.1 [Basic CPU Time], page 371, is specified by the ANSI C standard. The times function is a feature of POSIX.1. In the GNU system, the value returned by the clock function is equivalent to the sum of the tms_utime and tms_stime fields returned by times.

19.2 Calendar Time

This section describes facilities for keeping track of dates and times according to the Gregorian calendar.

There are three representations for date and time information:

- Calendar time (the time_t data type) is a compact representation, typically giving the number of seconds elapsed since some implementation-specific base time.
- There is also a high-resolution time representation (the struct timeval data type) that includes fractions of a second. Use this time representation instead of ordinary calendar time when you need greater precision.
- Local time or broken-down time (the struct tm data type) represents the date and time as a set of components specifying the year, month, and so on, for a specific time zone. This time representation is usually used in conjunction with formatting date and time values.

19.2.1 Simple Calendar Time

This section describes the time_t data type for representing calendar time, and the functions which operate on calendar time objects. These facilities are declared in the header file 'time.h'.

time_t Data Type

This is the data type used to represent calendar time. In the GNU C library and other POSIX-compliant implementations, time_t is equivalent to long int. When interpreted as an absolute time value, it represents the number of seconds elapsed since 00:00:00 on January 1, 1970, Coordinated Universal Time. (This date is sometimes referred to as the epoch.)

In other systems, time_t might be either an integer or floating-point type.

double difftime (time_t time1, time_t time0)

Function

The difftime function returns the number of seconds elapsed between time *time1* and time *time0*, as a value of type double.

In the GNU system, you can simply subtract time_t values. But on other systems, the time_t data type might use some other encoding where subtraction doesn't work directly.

time_t time (time_t *result)

Function

The time function returns the current time as a value of type time_t. If the argument result is not a null pointer, the time value is also stored in *result. If the calendar time is not available, the value (time_t)(-1) is returned.

19.2.2 High-Resolution Calendar

The time_t data type used to represent calendar times has a resolution of only one second. Some applications need more precision.

So, the GNU C library also contains functions which are capable of representing calendar times to a higher resolution than one second. The functions and the associated data types described in this section are declared in 'sys/time.h'.

struct timeval Data Type

The struct timeval structure represents a calendar time. It has the following members:

long int tv_sec

This represents the number of seconds since the epoch. It is equivalent to a normal time_t value.

long int tv_usec

This is the fractional second value, represented as the number of microseconds.

Some times struct timeval values are user for time intervals. Then the tv_sec member is the number of seconds in the interval, and tv_usec is the number of addictional microseconds.

376 The GNU C Library

struct timezone Data Type

The struct timezone structure is used to hold minimal information about the local time zone. It has the following members:

```
int tz_minuteswest
```

This is the number of minutes west of GMT.

```
int tz_dsttime
```

If nonzero, daylight savings time applies during some part of the year.

It is often necessary to subtract two values of type struct timeval. Here is the best way to do this. It works even on some peculiar operating systems where the tv_sec member has an unsigned type.

```
/* Subtract the 'struct timeval' values X and Y,
   storing the result in RESULT.
   Return 1 if the difference is negative, otherwise 0. */
int
timeval_subtract (result, x, y)
     struct timeval *result, *x, *y;
  /* Perform the carry for the later subtraction by updating y. */
  if (x->tv_usec < y->tv_usec) {
    int nsec = (y->tv\_usec - x->tv\_usec) / 1000000 + 1;
    y->tv_usec -= 1000000 * nsec;
    y->tv_sec += nsec;
  if (x->tv_usec - y->tv_usec > 1000000) {
    int nsec = (y->tv\_usec - x->tv\_usec) / 1000000;
    y->tv_usec += 1000000 * nsec;
    y->tv_sec -= nsec;
  /* Compute the time remaining to wait.
     tv_usec is certainly positive. */
  result->tv_sec = x->tv_sec - y->tv_sec;
  result->tv_usec = x->tv_usec - y->tv_usec;
  /* Return 1 if result is negative. */
  return x->tv_sec < y->tv_sec;
}
```

int gettimeofday (struct timeval *tp, struct timezone *tzp)

Function

The gettimeofday function returns the current date and time in the struct timeval structure indicated by tp. Information about the time zone is returned in the structure pointed at tzp. If the tzp argument is a null pointer, time zone information is ignored.

The return value is 0 on success and -1 on failure. The following errno error condition is defined for this function:

ENOSYS

The operating system does not support getting time zone information, and tzp is not a null pointer. The GNU operating system does not support using struct timezone to represent time zone information. Use tzname et al instead. Say something more helpful here.

int settimeofday (const struct timeval *tp, const struct timezone *tzp)

Function

The settimeofday function sets the current date and time according to the arguments. As for gettimeofday, time zone information is ignored if tzp is a null pointer.

You must be a privileged user in order to use settimeofday.

The return value is 0 on success and -1 on failure. The following errno error conditions are defined for this function:

EPERM This process cannot set the time because it is not privileged.

ENOSYS The operating system does not support setting time zone information, and tzp is not a null pointer.

int adjtime (const struct timeval *delta, struct timeval *olddelta) Function

This function speeds up or slows down the system clock in order to make gradual adjustments in the current time. This ensures that the time reported by the system clock is always monotonically increasing, which might not happen if you simply set the current time.

The delta argument specifies a relative adjustment to be made to the current time. If negative, the system clock is slowed down for a while until it has lost this much time. If positive, the system clock is speeded up for a while.

If the *olddelta* argument is not a null pointer, the **adjtime** function returns information about any previous time adjustment that has not yet completed.

This function is typically used to synchronize the clocks of computers in a local network. You must be a privileged user to use it. The return value is 0 on success and -1 on failure. The following errno error condition is defined for this function:

EPERM You do not have privilege to set the time.

Portability Note: The gettimeofday, settimeofday, and adjtime functions are derived from BSD.

19.2.3 Broken-down Time

Calender time is represented as a number of seconds. This is convenient for calculation, but has no resemblance to the way people normally represent dates and times. By contrast, broken-down time is a binary representation separated into year, month, day, and so on. Broken down time values are not useful for calculations, but they are useful for printing human readable time.

A broken-down time value is always relative to a choice of local time zone, and it also indicates which time zone was used.

The symbols in this section are declared in the header file 'time.h'.

struct tm Data Type

This is the data type used to represent a broken-down time. The structure contains at least the following members, which can appear in any order:

int tm_sec

This is the number of seconds after the minute, normally in the range 0 to 59. (The actual upper limit is 61, to allow for "leap seconds".)

int tm_min

This is the number of minutes after the hour, in the range 0 to 59.

int tm hour

This is the number of hours past midnight, in the range 0 to 23.

int tm_mday

This is the day of the month, in the range 1 to 31.

int tm_mon

This is the number of months since January, in the range 0 to 11.

int tm_year

This is the number of years since 1900.

int tm_wday

This is the number of days since Sunday, in the range 0 to 6.

int tm_yday

This is the number of days since January 1, in the range 0 to 365.

int tm_isdst

This is a flag that indicates whether Daylight Saving Time is (or was, or will be) in effect at the time described. The value is positive if Daylight Saving Time is in effect, zero if it is not, and negative if the information is not available.

long int tm_gmtoff

This field describes the time zone that was used to compute this broken-down time value; it is the amount you must add to the local time in that zone to get GMT, in units of seconds. The value is like that of the variable timezone (see Section 19.2.6 [Time Zone Functions], page 385). You can also think of this as the "number of seconds west" of GMT. The tm_gmtoff field is a GNU library extension.

const char *tm_zone

This field is the three-letter name for the time zone that was used to compute this broken-down time value. It is a GNU library extension.

struct tm * localtime (const time_t *time)

Function

The localtime function converts the calendar time pointed to by *time* to broken-down time representation, expressed relative to the user's specified time zone.

The return value is a pointer to a static broken-down time structure, which might be overwritten by subsequent calls to any of the date and time functions. (But no other library function overwrites the contents of this object.)

Calling localtime has one other effect: it sets the variable tzname with information about the current time zone. See Section 19.2.6 [Time Zone Functions], page 385.

struct tm * gmtime (const time_t *time)

Function

This function is similar to localtime, except that the broken-down time is expressed as Coordinated Universal Time (UTC)—that is, as Greenwich Mean Time (GMT) rather than relative to the local time zone.

Recall that calendar times are always expressed in coordinated universal time.

time_t mktime (struct tm *brokentime)

Function

The mktime function is used to convert a broken-down time structure to a calendar time representation. It also "normalizes" the contents of the broken-down time structure, by filling in the day of week and day of year based on the other date and time components.

The mktime function ignores the specified contents of the tm_wday and tm_yday members of the broken-down time structure. It uses the values of the other components to compute the calendar time; it's permissible for these components to have unnormalized values outside of their normal ranges. The last thing that mktime does is adjust the components of the brokentime structure (including the tm_wday and tm_yday).

If the specified broken-down time cannot be represented as a calendar time, mktime returns a value of (time_t)(-1) and does not modify the contents of brokentime.

Calling mktime also sets the variable tzname with information about the current time zone. See Section 19.2.6 [Time Zone Functions], page 385.

19.2.4 Formatting Date and Time

The functions described in this section format time values as strings. These functions are declared in the header file 'time.h'.

char * asctime (const struct tm *brokentime)

Function

The asctime function writes the broken-down time value pointed at by brokentime into a string in a standard format:

"Tue May 21 13:46:22 1991\n"

The abbreviations for the days of week are: 'Sun', 'Mon', 'Tue', 'Wed', 'Thu', 'Fri', and 'Sat'.

The abbreviations for the months are: 'Jan', 'Feb', 'Mar', 'Apr', 'May', 'Jun', 'Jul', 'Aug', 'Sep', 'Oct', 'Nov', and 'Dec'.

The return value points to a statically allocated string, which might be overwritten by subsequent calls to any of the date and time functions. (But no other library function overwrites the contents of this string.)

char * ctime (const time_t *time)

Function

The ctime function is similar to asctime, except that the time value is specified in calendar time (rather than local time) format. It is equivalent to

```
asctime (localtime (time))
```

ctime sets the variable tzname, because localtime does so. See Section 19.2.6 [Time Zone Functions], page 385.

This function is similar to the **sprintf** function (see Section 11.11 [Formatted Input], page 173), but the conversion specifications that can appear in the format template template are specialized for printing components of the date and time brokentime according to the locale currently specified for time conversion (see Chapter 7 [Locales], page 97).

Ordinary characters appearing in the *template* are copied to the output string s; this can include multibyte character sequences. Conversion specifiers are introduced by a '%' character, and are replaced in the output string as follows:

- %a The abbreviated weekday name according to the current locale.
- %A The full weekday name according to the current locale.
- **The abbreviated month name according to the current locale.**
- The full month name according to the current locale.
- %c The preferred date and time representation for the current locale.

%d	The day of the month as a decimal number (range 01 to 31).
% α	The day of the month as a decimal number (range of to 31).
%Н	The hour as a decimal number, using a 24-hour clock (range 00 to 23).
% I	The hour as a decimal number, using a 12-hour clock (range 01 to 12).
% j	The day of the year as a decimal number (range 001 to 366).
% m	The month as a decimal number (range 01 to 12).
% M	The minute as a decimal number.
%р	Either 'am' or 'pm', according to the given time value; or the corresponding strings for the current locale.
%S	The second as a decimal number.
% U	The week number of the current year as a decimal number, starting with the first Sunday as the first day of the first week.
% W	The week number of the current year as a decimal number, starting with the first Monday as the first day of the first week.
%w	The day of the week as a decimal number, Sunday being 0.
%x	The preferred date representation for the current locale, but without the time.
%X	The preferred time representation for the current locale, but with no date.
%у	The year as a decimal number, but without a century (range 00 to 99).
% Y	The year as a decimal number, including the century.
%Z	The time zone or name or abbreviation (empty if the time zone can't be determined).
%%	A literal '%' character.

The size parameter can be used to specify the maximum number of characters to be stored in the array s, including the terminating null character. If the formatted time requires more than size characters, the excess characters are discarded. The return value from **strftime** is the number of characters placed in the array s, not including the terminating null character. If the value equals size, it means that the array s was too small; you should repeat the call, providing a bigger array.

For an example of strftime, see Section 19.2.7 [Time Functions Example], page 386.

19.2.5 Specifying the Time Zone with TZ

In the GNU system, a user can specify the time zone by means of the TZ environment variable. For information about how to set environment variables, see Section 22.2 [Environment Variables], page 472. The functions for accessing the time zone are declared in 'time.h'.

The value of the TZ variable can be of one of three formats. The first format is used when there is no Daylight Saving Time (or summer time) in the local time zone:

std offset

The std string specifies the name of the time zone. It must be three or more characters long and must not contain a leading colon or embedded digits, commas, or plus or minus signs. There is no space character separating the time zone name from the offset, so these restrictions are necessary to parse the specification correctly.

The offset specifies the time value one must add to the local time to get a Coordinated Universal Time value. It has syntax like [+|-]hh[:mm[:ss]]. This is positive if the local time zone is west of the Prime Meridian and negative if it is east. The hour must be between 0 and 24, and the minute and seconds between 0 and 59.

For example, here is how we would specify Eastern Standard Time, but without any daylight savings time alternative:

EST+5

The second format is used when there is Daylight Saving Time:

std offset dst [offset], start[/time], end[/time]

The initial std and offset specify the standard time zone, as described above. The dst string and offset specify the name and offset for the corresponding daylight savings time time zone; if the offset is omitted, it defaults to one hour ahead of standard time.

The GNU C Library

The remainder of the specification describes when daylight savings time is in effect. The *start* field is when daylight savings time goes into effect and the *end* field is when the change is made back to standard time. The following formats are recognized for these fields:

Jn This specifies the Julian day, with n between 1 and 365. February 29 is never counted, even in leap years.

n This specifies the Julian day, with n between 0 and 365. February 29 is counted in leap years.

Mm.w.d This specifies day d of week w of month m. The day d must be between 0 (Sunday) and 6. The week w must be between 1 and 5; week 1 is the first week in which day d occurs, and week 5 specifies the last d day in the month. The month m should be between 1 and 12.

The *time* fields specify when, in the local time currently in effect, the change to the other time occurs. If omitted, the default is 02:00:00.

For example, here is how one would specify the Eastern time zone in the United States, including the appropriate daylight saving time and its dates of applicability. The normal offset from GMT is 5 hours; since this is west of the prime meridian, the sign is positive. Summer time begins on the first Sunday in April at 2:00am, and ends on the last Sunday in October at 2:00am.

EST+5EDT, M4.1.0/M10.5.0

The schedule of daylight savings time in any particular jurisdiction has changed over the years. To be strictly correct, the conversion of dates and times in the past should be based on the schedule that was in effect then. However, the system has no facilities to let you specify how the schedule has changed from year to year. The most you can do is specify one particular schedule—usually the present day schedule—and this is used to convert any date, no matter when.

The third format looks like this:

: characters

384

Each operating system interprets this format differently; in the GNU C library, characters is the name of a file which describes the time zone.

If the TZ environment variable does not have a value, the operation chooses a time zone by default. Each operating system has its own rules for choosing the default time zone, so there is little we can say about them.

19.2.6 Functions and Variables for Time Zones

char *tzname[2] Variable

The array tzname contains two strings, which are the standard three-letter names of the pair of time zones (standard and daylight savings) that the user has selected. tzname [0] is the name of the standard time zone (for example, "EST"), and tzname [1] is the name for the time zone when daylight savings time is in use (for example, "EDT"). These correspond to the std and dst strings (respectively) from the TZ environment variable.

The tzname array is initialized from the TZ environment variable whenever tzset, ctime, strftime, mktime, or localtime is called.

void tzset (void) Function

The tzset function initializes the tzname variable from the value of the TZ environment variable. It is not usually necessary for your program to call this function, because it is called automatically when you use the other time conversion functions that depend on the time zone.

The following variables are defined for compatibility with System V Unix. These variables are set by calling localtime.

long int timezone

Variable

This contains the difference between GMT and local standard time, in seconds. For example, in the U.S. Eastern time zone, the value is 5*60*60.

int daylight Variable

This variable has a nonzero value if the standard U.S. daylight savings time rules apply.

19.2.7 Time Functions Example

Here is an example program showing the use of some of the local time and calendar time functions.

```
#include <time.h>
#include <stdio.h>
#define SIZE 256
int
main (void)
  char buffer[SIZE];
  time_t curtime;
  struct tm *loctime;
  /* Get the current time. */
  curtime = time (NULL);
  /* Convert it to local time representation. */
  loctime = localtime (&curtime);
  /* Print out the date and time in the standard format. */
  fputs (asctime (loctime), stdout);
  /* Print it out in a nice format. */
  strftime (buffer, SIZE, "Today is %A, %B %d.\n", loctime);
  fputs (buffer, stdout);
  strftime (buffer, SIZE, "The time is %I:%M %p.\n", loctime);
  fputs (buffer, stdout);
  return 0;
}
```

It produces output like this:

```
Wed Jul 31 13:02:36 1991
Today is Wednesday, July 31.
The time is 01:02 PM.
```

19.3 Setting an Alarm

The alarm and setitimer functions provide a mechanism for a process to interrupt itself at some future time. They do this by setting a timer; when the timer expires, the process recieves a signal.

Each process has three independent interval timers available:

- A real-time timer that counts clock time. This timer sends a SIGALRM signal to the process when it expires.
- A virtual timer that counts CPU time used by the process. This timer sends a SIGVTALRM signal to the process when it expires.
- A profiling timer that counts both CPU time used by the process, and CPU time spent in system calls on behalf of the process. This timer sends a SIGPROF signal to the process when it expires.

You can only have one timer of each kind set at any given time. If you set a timer that has not yet expired, that timer is simply reset to the new value.

You should establish a handler for the appropriate alarm signal using signal or sigaction before issuing a call to setitimer or alarm. Otherwise, an unusual chain of events could cause the timer to expire before your program establishes the handler, and in that case it would be terminated, since that is the default action for the alarm signals. See Chapter 21 [Signal Handling], page 403.

The setitimer function is the primary means for setting an alarm. This facility is declared in the header file 'sys/time.h'. The alarm function, declared in 'unistd.h', provides a somewhat simpler interface for setting the real-time timer.

struct itimerval Data Type

This structure is used to specify when a timer should expire. It contains the following members:

struct timeval it_interval

This is the interval between successive timer interrupts. If zero, the alarm will only be sent once.

struct timeval it_value

This is the interval to the first timer interrupt. If zero, the alarm is disabled.

The struct timeval data type is described in Section 19.2.2 [High-Resolution Calendar], page 375.

The setitimer function sets the timer specified by which according to new. The which argument can have a value of ITIMER_REAL, ITIMER_VIRTUAL, or ITIMER_PROF.

If old is not a null pointer, setitimer returns information about any previous unexpired timer of the same kind in the structure it points to.

The return value is 0 on success and -1 on failure. The following errno error conditions are defined for this function:

EINVAL The timer interval was too large.

int getitimer (int which, struct itimerval *old)

Function

The getitimer function stores information about the timer specified by which in the structure pointed at by old.

The return value and error conditions are the same as for setitimer.

ITIMER_REAL

This constant can be used as the *which* argument to the setitimer and getitimer functions to specify the real-time timer.

ITIMER_VIRTUAL

This constant can be used as the *which* argument to the **setitimer** and **getitimer** functions to specify the virtual timer.

ITIMER_PROF

This constant can be used as the which argument to the setitimer and getitimer functions to specify the profiling timer.

```
unsigned int alarm (unsigned int seconds)
```

Function

The alarm function sets the real-time timer to expire in seconds seconds. If you want to cancel any existing alarm, you can do this by calling alarm with a seconds argument of zero.

The return value indicates how many seconds remain before the previous alarm would have been sent. If there is no previous alarm, alarm returns zero.

The alarm function could be defined in terms of setitimer like this:

```
unsigned int
alarm (unsigned int seconds)
{
   struct itimerval old, new;
   new.it_interval.tv_usec = 0;
   new.it_interval.tv_sec = 0;
   new.it_value.tv_usec = 0;
   new.it_value.tv_sec = (long int) seconds;
   if (setitimer (ITIMER_REAL, &new, &old) < 0)
      return 0;
   else
      return old.it_value.tv_sec;
}</pre>
```

There is an example showing the use of the alarm function in Section 21.4.1 [Handler Returns], page 426.

If you simply want your process to wait for a given number of seconds, you should use the sleep function. See Section 19.4 [Sleeping], page 390.

You shouldn't count on the signal arriving precisely when the timer expires. In a multiprocessing environment there is typically some amount of delay involved.

Portability Note: The setitimer and getitimer functions are derived from BSD Unix, while the alarm function is specified by the POSIX.1 standard. setitimer is more powerful than alarm, but alarm is more widely used.

The GNU C Library

19.4 Sleeping

The function sleep gives a simple way to make the program wait for short periods of time. If your program doesn't use signals (except to terminate), then you can expect sleep to wait reliably for the specified amount of time. Otherwise, sleep can return sooner if a signal arrives; if you want to wait for a given period regardless of signals, use select (see Section 12.6 [Waiting for I/O], page 215) and don't specify any descriptors to wait for.

unsigned int sleep (unsigned int seconds)

Function

The sleep function waits for seconds or until a signal is delivered, whichever happens first.

If sleep function returns because the requested time has elapsed, it returns a value of zero. If it returns because of delivery of a signal, its return value is the remaining time in the sleep period.

The sleep function is declared in 'unistd.h'.

Resist the temptation to implement a sleep for a fixed amount of time by using the return value of sleep, when nonzero, to call sleep again. This will work with a certain amount of accuracy as long as signals arrive infrequently. But each signal can cause the eventual wakeup time to be off by an additional second or so. Suppose a few signals happen to arrive in rapid succession by bad luck—there is no limit on how much this could shorten or lengthen the wait.

Instead, compute the time at which the program should stop waiting, and keep trying to wait until that time. This won't be off by more than a second. With just a little more work, you can use select and make the waiting period quite accurate. (Of course, heavy system load can cause unavoidable additional delays—unless the machine is dedicated to one application, there is no way you can avoid this.)

On some systems, sleep can do strange things if your program uses SIGALRM explicitly. Even if SIGALRM signals are being ignored or blocked when sleep is called, sleep might return prematurely on delivery of a SIGALRM signal. If you have established a handler for SIGALRM signals and a SIGALRM signal is delivered while the process is sleeping, the action taken might be just to cause sleep to return instead of invoking your handler. And, if sleep is interrupted by delivery of a signal whose handler requests an alarm or alters the handling of SIGALRM, this handler and sleep will interfere.

On the GNU system, it is safe to use sleep and SIGALRM in the same program, because sleep does not work by means of SIGALRM.

19.5 Resource Usage

The function getrusage and the data type struct rusage are used for examining the usage figures of a process. They are declared in 'sys/resource.h'.

int getrusage (int processes, struct rusage *rusage)

Function

This function reports the usage totals for processes specified by *processes*, storing the information in *rusage.

In most systems, processes has only two valid values:

RUSAGE_SELF

Just the current process.

RUSAGE_CHILDREN

All child processes (direct and indirect) that have terminated already.

In the GNU system, you can also inquire about a particular child process by specifying its process ID.

The return value of getrusage is zero for success, and -1 for failure.

EINVAL The argument processes is not valid.

One way of getting usage figures for a particular child process is with the function wait4, which returns totals for a child when it terminates. See Section 23.8 [BSD Wait Functions], page 491.

struct rusage Data Type

This data type records a collection usage amounts for various sorts of resources. It has the following members, and possibly others:

struct timeval ru_utime

User time used.

struct timeval ru_stime

System time used.

long ru_majflt

Number of page faults.

long ru_inblock

Number of block input operations.

long ru_oublock

Number of block output operations.

long ru_msgsnd

Number of messages sent.

long ru_msgrcv

Number of messages received.

long ru_nsignals

Number of signals received.

An additional historical function for examining usage figures, vtimes, is supported but not documented here. It is declared in 'sys/vtimes.h'.

19.6 Limiting Resource Usage

You can specify limits for the resource usage of a process. When the process tries to exceed a limit, it may get a signal, or the system call by which it tried to do so may fail, depending on the limit. Each process initially inherits its limit values from its parent, but it can subsequently change them.

The symbols in this section are defined in 'sys/resource.h'.

int getrlimit (int resource, struct rlimit *rlp)

Function

Read the current value and the maximum value of resource resource and store them in *rlp.

The return value is 0 on success and -1 on failure. The only possible errno error condition is EFAULT.

int setrlimit (int resource, struct rlimit *rlp)

Function

Store the current value and the maximum value of resource resource in *rlp.

The return value is 0 on success and -1 on failure. The following errno error condition is possible:

EPERM You tried to change the maximum permissible limit value, but you don't have privileges to do so.

struct rlimit Data Type

This structure is used with getrlimit to receive limit values, and with setrlimit to specify limit values. It has two fields:

rlim_cur The current value of the limit in question.

rlim_max The maximum permissible value of the limit in question. You cannot set the current value of the limit to a larger number than this maximum. Only the super user can change the maximum permissible value.

In getrlimit, the structure is an output; it receives the current values. In setrlimit, it specifies the new values.

Here is a list of resources that you can specify a limit for. Those that are sizes are measured in bytes.

RLIMIT_CPU

The maximum amount of cpu time the process can use. If it runs for longer than this, it gets a signal: SIGXCPU. The value is measured in seconds. See Section 21.2.7 [Nonstandard Signals], page 414.

RLIMIT_FSIZE

The maximum size of file the process can create. Trying to write a larger file causes a signal: SIGXFSZ. See Section 21.2.7 [Nonstandard Signals], page 414.

RLIMIT_DATA

The maximum size of data memory for the process. If the process tries to allocate data memory beyond this amount, the allocation function fails.

394 The GNU C Library

RLIMIT_STACK

The maximum stack size for the process. If the process tries to extend its stack past this size, it gets a SIGSEGV signal. See Section 21.2.1 [Program Error Signals], page 406.

RLIMIT_CORE

The maximum size core file that this process can create. If the process terminates and a core file is made, and this maximum size is not enough, the core file is truncated.

RLIMIT_RSS

The maximum amount of physical memory that this process should get. This parameter is a guide for the system's scheduler and memory allocator; the system may give the process more memory when there is a surplus.

RLIMIT_OPEN_FILES

The maximum number of files that the process can open. If it tries to open more files than this, it gets error code EMFILE. See Section 2.2 [Error Codes], page 17.

RLIM_NLIMITS

The number of different resource limits. Any valid *resource* operand must be less than RLIM_NLIMITS.

int RLIM_INFINITY Constant

This constant stands for a value of "infinity" when supplied as the limit value in setrlimit.

Two historical functions for setting resource limits, ulimit and vlimit, are not documented here. The latter is declared in 'sys/vlimit.h' and comes from BSD.

19.7 Process Priority

When several processes try to run, their respective priorities determine what share of the CPU each process gets. This section describes how you can read and set the priority of a process. All these functions and macros are declared in 'sys/resource.h'.

The range of valid priority values depends on the operating system, but typically it runs from -20 to 20. A lower priority value means the process runs more often. These constants describe the range of priority values:

PRIO_MIN The smallest valid priority value.

PRIO_MAX The smallest valid priority value.

int getpriority (int class, int id)

Function

Read the priority of a class of processes; class and id specify which ones (see below).

The return value is the priority value on success, and -1 on failure. The following errno error condition are possible for this function:

ESRCH The combination of *class* and *id* does not match any existing process.

EINVAL The value of class is not valid.

When the return value is -1, it could indicate failure, or it could be the priority value. The only way to make certain is to set errno = 0 before calling getpriority, then use errno != 0 afterward as the criterion for failure.

int setpriority (int class, int id, int priority)

Function

Read the priority of a class of processes; class and id specify which ones (see below).

The return value is 0 on success and -1 on failure. The following errno error condition are defined for this function:

ESRCH The combination of class and id does not match any existing process.

EINVAL The value of class is not valid.

EPERM You tried to set the priority of some other user's process, and you don't

have privileges for that.

EACCES You tried to lower the priority of a process, and you don't have privileges

for that.

The arguments *class* and *id* together specify a set of processes you are interested in. These are the possible values for *class*:

PRIO_PROCESS

Read or set the priority of one process. The argument id is a process ID.

396 The GNU C Library

PRIO_PGRP

Read or set the priority of one process group. The argument id is a process group ID. PRIO_USER

Read or set the priority of one user's processes. The argument id is a user ID.

If the argument id is 0, it stands for the current process, current process group, or the current user, according to class.

```
int nice (int increment)
```

Function

Increment the priority of the current process by *increment*. The return value is not meaningful.

Here is an equivalent definition for nice:

```
int
nice (int increment)
{
  int old = getpriority (PRIO_PROCESS, 0);
  setpriority (PRIO_PROCESS, 0, old + increment);
}
```

20 Non-Local Exits

Sometimes when your program detects an unusual situation inside a deeply nested set of function calls, you would like to be able to immediately return to an outer level of control. This section describes how you can do such *non-local exits* using the setjmp and longjmp functions.

20.1 Introduction to Non-Local Exits

As an example of a situation where a non-local exit can be useful, suppose you have an interactive program that has a "main loop" that prompts for and executes commands. Suppose the "read" command reads input from a file, doing some lexical analysis and parsing of the input while processing it. If a low-level input error is detected, it would be useful to be able to return immediately to the "main loop" instead of having to make each of the lexical analysis, parsing, and processing phases all have to explicitly deal with error situations initially detected by nested calls.

(On the other hand, if each of these phases has to do a substantial amount of cleanup when it exits—such as closing files, deallocating buffers or other data structures, and the like—then it can be more appropriate to do a normal return and have each phase do its own cleanup, because a non-local exit would bypass the intervening phases and their associated cleanup code entirely. Alternatively, you could use a non-local exit but do the cleanup explicitly either before or after returning to the "main loop".)

In some ways, a non-local exit is similar to using the 'return' statement to return from a function. But while 'return' abandons only a single function call, transferring control back to the point at which it was called, a non-local exit can potentially abandon many levels of nested function calls.

You identify return points for non-local exits calling the function setjmp. This function saves information about the execution environment in which the call to setjmp appears in an object of type jmp_buf. Execution of the program continues normally after the call to setjmp, but if a exit is later made to this return point by calling longjmp with the corresponding jmp_buf object, control is transferred back to the point where setjmp was called. The return value from setjmp is used to distinguish between an ordinary return and a return made by a call to longjmp, so calls to setjmp usually appear in an 'if' statement.

Here is how the example program described above might be set up:

```
#include <setjmp.h>
#include <stdlib.h>
#include <stdio.h>
jmp_buf main_loop;
void
abort_to_main_loop (int status)
  longjmp (main_loop, status);
}
int
main (void)
 while (1)
    if (setjmp (main_loop))
      puts ("Back at main loop....");
    else
      do_command ();
}
void
do_command (void)
  char buffer[128];
  if (fgets (buffer, 128, stdin) == NULL)
    abort_to_main_loop (-1);
  else
    exit (EXIT_SUCCESS);
}
```

The function abort_to_main_loop causes an immediate transfer of control back to the main loop of the program, no matter where it is called from.

The flow of control inside the main function may appear a little mysterious at first, but it is actually a common idiom with setjmp. A normal call to setjmp returns zero, so the "else" clause of the conditional is executed. If abort_to_main_loop is called somewhere within the execution of do_command, then it actually appears as if the same call to setjmp in main were returning a second time with a value of -1.

So, the general pattern for using setjmp looks something like:

```
if (setjmp (buffer))
  /* Code to clean up after premature return. */
...
else
  /* Code to be executed normally after setting up the return point. */
...
```

20.2 Details of Non-Local Exits

Here are the details on the functions and data structures used for performing non-local exits. These facilities are declared in 'setjmp.h'.

jmp_buf Data Type

Objects of type jmp_buf hold the state information to be restored by a non-local exit. The contents of a jmp_buf identify a specific place to return to.

int setjmp (jmp_buf state)

Macro

When called normally, setjmp stores information about the execution state of the program in *state* and returns zero. If longjmp is later used to perform a non-local exit to this *state*, setjmp returns a nonzero value.

void longjmp (jmp_buf state, int value)

Function

This function restores current execution to the state saved in *state*, and continues execution from the call to setjmp that established that return point. Returning from setjmp by means of longjmp returns the *value* argument that was passed to longjmp, rather than 0. (But if *value* is given as 0, setjmp returns 1).

There are a lot of obscure but important restrictions on the use of setjmp and longjmp. Most of these restrictions are present because non-local exits require a fair amount of magic on the part of the C compiler and can interact with other parts of the language in strange ways.

The setjmp function is actually a macro without an actual function definition, so you shouldn't try to '#undef' it or take its address. In addition, calls to setjmp are safe in only the following contexts:

• As the test expression of a selection or iteration statement (such as 'if' or 'while').

- As one operand of a equality or comparison operator that appears as the test expression of a selection or iteration statement. The other operand must be an integer constant expression.
- As the operand of a unary '!' operator, that appears as the test expression of a selection or iteration statement.
- By itself as an expression statement.

Return points are valid only during the dynamic extent of the function that called **setjmp** to establish them. If you **longjmp** to a return point that was established in a function that has already returned, unpredictable and disastrous things are likely to happen.

You should use a nonzero value argument to longjmp. While longjmp refuses to pass back a zero argument as the return value from setjmp, this is intended as a safety net against accidental misuse and is not really good programming style.

When you perform a non-local exit, accessible objects generally retain whatever values they had at the time longjmp was called. The exception is that the values of automatic variables local to the function containing the setjmp call that have been changed since the call to setjmp are indeterminate, unless you have declared them volatile.

20.3 Non-Local Exits and Signals

In BSD Unix systems, setjmp and longjmp also save and restore the set of blocked signals; see Section 21.7 [Blocking Signals], page 445. However, the POSIX.1 standard requires setjmp and longjmp not to change the set of blocked signals, and provides an additional pair of functions (sigsetjmp and sigsetjmp) to get the BSD behavior.

The behavior of setjmp and longjmp in the GNU library is controlled by feature test macros; see Section 1.3.4 [Feature Test Macros], page 9. The default in the GNU system is the POSIX.1 behavior rather than the BSD behavior.

The facilities in this section are declared in the header file 'setjmp.h'.

sigjmp_buf

Data Type

This is similar to jmp_buf, except that it can also store state information about the set of blocked signals.

int sigsetjmp (sigjmp_buf state, int savesigs)

Function

This is similar to setjmp. If savesigs is nonzero, the set of blocked signals is saved in state and will be restored if a siglongjmp is later performed with this state.

void siglongjmp (sigjmp_buf state, int value)

Function

This is similar to longjmp except for the type of its *state* argument. If the sigsetjmp call that set this *state* used a nonzero *savesigs* flag, siglongjmp also restores the set of blocked signals.

402

21 Signal Handling

A signal is a software interrupt delivered to a process. The operating system uses signals to report exceptional situations to an executing program. Some signals report errors such as references to invalid memory addresses; others report asynchronous events, such as disconnection of a phone line.

The GNU C library defines a variety of signal types, each for a particular kind of event. Some kinds of events make it inadvisable or impossible for the program to proceed as usual, and the corresponding signals normally abort the program. Other kinds of signals that report harmless events are ignored by default.

If you anticipate an event that causes signals, you can define a handler function and tell the operating system to run it when that particular type of signal arrives.

Finally, one process can send a signal to another process; this allows a parent process to abort a child, or two related processes to communicate and synchronize.

21.1 Basic Concepts of Signals

This section explains basic concepts of how signals are generated, what happens after a signal is delivered, and how programs can handle signals.

21.1.1 Some Kinds of Signals

A signal reports the occurrence of an exceptional event. These are some of the events that can cause (or *generate*, or *raise*) a signal:

- A program error such as dividing by zero or issuing an address outside the valid range.
- A user request to interrupt or terminate the program. Most environments are set up to let a user suspend the program by typing C-z, or terminate it with C-c. Whatever key sequence is used, the operating system sends the proper signal to interrupt the process.
- The termination of a child process.
- Expiration of a timer or alarm.
- A call to kill or raise by the same process.

• A call to kill from another process. Signals are a limited but useful form of interprocess communication.

Each of these kinds of events (excepting explicit calls to kill and raise) generates its own particular kind of signal. The various kinds of signals are listed and described in detail in Section 21.2 [Standard Signals], page 406.

21.1.2 Concepts of Signal Generation

In general, the events that generate signals fall into three major categories: errors, external events, and explicit requests.

An error means that a program has done something invalid and cannot continue execution. But not all kinds of errors generate signals—in fact, most do not. For example, opening a nonexistant file is an error, but it does not raise a signal; instead, open returns -1. In general, errors that are necessarily associated with certain library functions are reported by returning a value that indicates an error. The errors which raise signals are those which can happen anywhere in the program, not just in library calls. These include division by zero and invalid memory addresses.

An external event generally has to do with I/O or other processes. These include the arrival of input, the expiration of a timer, and the termination of a child process.

An explicit request means the use of a library function such as kill whose purpose is specifically to generate a signal.

Signals may be generated *synchronously* or *asynchronously*. A synchronous signal pertains to a specific action in the program, and is delivered (unless blocked) during that action. Errors generate signals synchronously, and so do explicit requests by a process to generate a signal for that same process.

Asynchronous signals are generated by events outside the control of the process that receives them. These signals arrive at unpredictable times during execution. External events generate signals asynchronously, and so do explicit requests that apply to some other process.

A given type of signal is either typically synchrous or typically asynchronous. For example, signals for errors are typically synchronous because errors generate signals synchronously. But any type of signal can be generated synchronously or asynchronously with an explicit request.

21.1.3 How Signals Are Delivered

When a signal is generated, it becomes *pending*. Normally it remains pending for just a short period of time and then is *delivered* to the process that was signaled. However, if that kind of signal is currently *blocked*, it may remain pending indefinitely—until signals of that kind are *unblocked*. Once unblocked, it will be delivered immediately. See Section 21.7 [Blocking Signals], page 445.

When the signal is delivered, whether right away or after a long delay, the specified action for that signal is taken. For certain signals, such as SIGKILL and SIGSTOP, the action is fixed, but for most signals, the program has a choice: ignore the signal, specify a handler function, or accept the default action for that kind of signal. The program specifies its choice using functions such as signal or sigaction (see Section 21.3 [Signal Actions], page 416). We sometimes say that a handler catches the signal. While the handler is running, that particular signal is normally blocked.

If the specified action for a kind of signal is to ignore it, then any such signal which is generated is discarded immediately. This happens even if the signal is also blocked at the time. A signal discarded in this way will never be delivered, not even if the program subsequently specifies a different action for that kind of signal and then unblocks it.

If a signal arrives which the program has neither handled nor ignored, its default action takes place. Each kind of signal has its own default action, documented below (see Section 21.2 [Standard Signals], page 406). For most kinds of signals, the default action is to terminate the process. For certain kinds of signals that represent "harmless" events, the default action is to do nothing.

When a signal terminates a process, its parent process can determine the cause of termination by examining the termination status code reported by the wait or waitpid functions. (This is discussed in more detail in Section 23.6 [Process Completion], page 488.) The information it can get includes the fact that termination was due to a signal, and the kind of signal involved. If a program you run from a shell is terminated by a signal, the shell typically prints some kind of error message.

The signals that normally represent program errors have a special property: when one of these signals terminates the process, it also writes a *core dump file* which records the state of the process at the time of termination. You can examine the core dump with a debugger to investigate what caused the error.

If you raise a "program error" signal by explicit request, and this terminates the process, it makes a core dump file just as if the signal had been due directly to an error.

21.2 Standard Signals

This section lists the names for various standard kinds of signals and describes what kind of event they mean. Each signal name is a macro which stands for a positive integer—the signal number for that kind of signal. Your programs should never make assumptions about the numeric code for a particular kind of signal, but rather refer to them always by the names defined here. This is because the number for a given kind of signal can vary from system to system, but the meanings of the names are standardized and fairly uniform.

The signal names are defined in the header file 'signal.h'.

int NSIG Macro

The value of this symbolic constant is the total number of signals defined. Since the signal numbers are allocated consecutively, NSIG is also one greater than the largest defined signal number.

21.2.1 Program Error Signals

The following signals are generated when a serious program error is detected by the operating system or the computer itself. In general, all of these signals are indications that your program is seriously broken in some way, and there's usually no way to continue the computation which encountered the error.

Some programs handle program error signals in order to tidy up before terminating; for example, programs that turn off echoing of terminal input should handle program error signals in order to turn echoing back on. The handler should end by specifying the default action for the signal that happened and then reraising it; this will cause the program to terminate with that signal, as if it had not had a handler. (See Section 21.4.2 [Termination in Handler], page 427.)

Termination is the sensible ultimate outcome from a program error in most programs. However, programming systems such as Lisp that can load compiled user programs might need to keep executing even if a user program incurs an error. These programs have handlers which use longjmp to return control to the command level.

The default action for all of these signals is to cause the process to terminate. If you block or ignore these signals or establish handlers for them that return normally, your program will probably break horribly when such signals happen, unless they are generated by raise or kill instead of a real error.

When one of these program error signals terminates a process, it also writes a core dump file which records the state of the process at the time of termination. The core dump file is named 'core' and is written in whichever directory is current in the process at the time. (On the GNU system, you can specify the file name for core dumps with the environment variable COREFILE.) The purpose of core dump files is so that you can examine them with a debugger to investigate what caused the error.

int SIGFPE Macro

The SIGFPE signal reports a fatal arithmetic error. Although the name is derived from "floating-point exception", this signal actually covers all arithmetic errors, including division by zero and overflow. If a program stores integer data in a location which is then used in a floating-point operation, this often causes an "invalid operation" exception, because the processor cannot recognize the data as a floating-point number.

Actual floating-point exceptions are a complicated subject because there are many types of exceptions with subtly different meanings, and the SIGFPE signal doesn't distinguish between them. The IEEE Standard for Binary Floating-Point Arithmetic (ANSI/IEEE Std 754-1985) defines various floating-point exceptions and requires conforming computer systems to report their occurrences. However, this standard does not specify how the exceptions are reported, or what kinds of handling and control the operating system can offer to the programmer.

BSD systems provide the SIGFPE handler with an extra argument that distinguishes various causes of the exception. In order to access this argument, you must define the handler to accept two arguments, which means you must cast it to a one-argument function type in order to establish the handler. The GNU library does provide this extra argument, but the value is meaningful only on operating systems that provide the information (BSD systems and GNU systems).

FPE_INTOVF_TRAP

Integer overflow (impossible in a C program unless you enable overflow trapping in a hardware-specific fashion).

FPE_INTDIV_TRAP

Integer division by zero.

FPE_SUBRNG_TRAP

Subscript-range (something that C programs never check for).

FPE_FLTOVF_TRAP

Floating overflow trap.

408 The GNU C Library

FPE_FLTDIV_TRAP

Floating/decimal division by zero.

FPE_FLTUND_TRAP

Floating underflow trap. (Trapping on floating underflow is not normally enabled.)

FPE_DECOVF_TRAP

Decimal overflow trap. (Only a few machines have decimal arithmetic and C never uses it.)

int SIGILL Macro

The name of this signal is derived from "illegal instruction"; it means your program is trying to execute garbage or a privileged instruction. Since the C compiler generates only valid instructions, SIGILL typically indicates that the executable file is corrupted, or that you are trying to execute data. Some common ways of getting into the latter situation are by passing an invalid object where a pointer to a function was expected, or by writing past the end of an automatic array (or similar problems with pointers to automatic variables) and corrupting other data on the stack such as the return address of a stack frame.

int SIGSEGV Macro

This signal is generated when a program tries to read or write outside the memory that is allocated for it. (Actually, the signals only occur when the program goes far enough outside to be detected by the system's memory protection mechanism.) The name is an abbreviation for "segmentation violation".

The most common way of getting a SIGSEGV condition is by dereferencing a null or uninitialized pointer. A null pointer refers to the address 0, and most operating systems make sure this address is always invalid precisely so that dereferencing a null pointer will cause SIGSEGV. (Some operating systems place valid memory at address 0, and dereferencing a null pointer does not cause a signal on these systems.) As for uninitialized pointer variables, they contain random addresses which may or may not be valid.

Another common way of getting into a SIGSEGV situation is when you use a pointer to step through an array, but fail to check for the end of the array.

int SIGBUS Macro

This signal is generated when an invalid pointer is dereferenced. Like SIGSEGV, this signal is typically the result of dereferencing an uninitialized pointer. The difference between the two is that SIGSEGV indicates an invalid access to valid memory, while SIGBUS indicates an access to an invalid address. In particular, SIGBUS signals often result from dereferencing a misaligned pointer, such as referring to a four-word integer at an address not divisible by four. (Each kind of computer has its own requirements for address alignment.)

The name of this signal is an abbreviation for "bus error".

int SIGABRT Macro

This signal indicates an error detected by the program itself and reported by calling abort. See Section 22.3.4 [Aborting a Program], page 479.

21.2.2 Termination Signals

These signals are all used to tell a process to terminate, in one way or another. They have different names because they're used for slightly different purposes, and programs might want to handle them differently.

The reason for handling these signals is usually so your program can tidy up as appropriate before actually terminating. For example, you might want to save state information, delete temporary files, or restore the previous terminal modes. Such a handler should end by specifying the default action for the signal that happened and then reraising it; this will cause the program to terminate with that signal, as if it had not had a handler. (See Section 21.4.2 [Termination in Handler], page 427.)

The (obvious) default action for all of these signals is to cause the process to terminate.

int SIGHUP Macro

The SIGHUP ("hang-up") signal is used to report that the user's terminal is disconnected, perhaps because a network or telephone connection was broken. For more information about this, see Section 16.4.6 [Control Modes], page 330.

This signal is also used to report the termination of the controlling process on a terminal to jobs associated with that session; this termination effectively disconnects all

processes in the session from the controlling terminal. For more information, see Section 22.3.5 [Termination Internals], page 479.

int SIGINT Macro

The SIGINT ("program interrupt") signal is sent when the user types the INTR character (normally C-c). See Section 16.4.9 [Special Characters], page 335, for information about terminal driver support for C-c.

int SIGQUIT Macro

The SIGQUIT signal is similar to SIGINT, except that it's controlled by a different key—the QUIT character, usually C-\—and produces a core dump when it terminates the process, just like a program error signal. You can think of this as a program error condition "detected" by the user.

See Section 21.2.1 [Program Error Signals], page 406, for information about core dumps. See Section 16.4.9 [Special Characters], page 335, for information about terminal driver support.

Certain kinds of cleanups are best omitted in handling SIGQUIT. For example, if the program creates temporary files, it should handle the other termination requests by deleting the temporary files. But it is better for SIGQUIT not to delete them, so that the user can examine them in conjunction with the core dump.

int SIGTERM Macro

The SIGTERM signal is a generic signal used to cause program termination. Unlike SIGKILL, this signal can be blocked, handled, and ignored.

The shell command kill generates SIGTERM by default.

int SIGKILL Macro

The SIGKILL signal is used to cause immediate program termination. It cannot be handled or ignored, and is therefore always fatal. It is also not possible to block this signal.

This signal is generated only by explicit request. Since it cannot be handled, you should generate it only as a last resort, after first trying a less drastic method such as C-c or SIGTERM. If a process does not respond to any other termination signals, sending it a SIGKILL signal will almost always cause it to go away.

In fact, if SIGKILL fails to terminate a process, that by itself constitutes an operating system bug which you should report.

21.2.3 Alarm Signals

These signals are used to indicate the expiration of timers. See Section 19.3 [Setting an Alarm], page 387, for information about functions that cause these signals to be sent.

The default behavior for these signals is to cause program termination. This default is rarely useful, but no other default would be useful; most of the ways of using these signals would require handler functions in any case.

int SIGALRM Macro

This signal typically indicates expiration of a timer that measures real or clock time. It is used by the alarm function, for example.

int SIGVTALRM Macro

This signal typically indicates expiration of a timer that measures CPU time used by the current process. The name is an abbreviation for "virtual time alarm".

int SIGPROF Macro

This signal is typically indicates expiration of a timer that measures both CPU time used by the current process, and CPU time expended on behalf of the process by the system. Such a timer is used to implement code profiling facilities, hence the name of this signal.

21.2.4 Asynchronous I/O Signals

The signals listed in this section are used in conjunction with asynchronous I/O facilities. You have to take explicit action by calling fcntl to enable a particular file description to generate these signals (see Section 12.12 [Interrupt Input], page 231). The default action for these signals is to ignore them.

int SIGIO Macro

This signal is sent when a file descriptor is ready to perform input or output.

On most operating systems, terminals and sockets are the only kinds of files that can generate SIGIO; other kinds, including ordinary files, never generate SIGIO even if you ask them to.

int SIGURG Macro

This signal is sent when "urgent" or out-of-band data arrives on a socket. See Section 15.8.8 [Out-of-Band Data], page 306.

21.2.5 Job Control Signals

These signals are used to support job control. If your system doesn't support job control, then these macros are defined but the signals themselves can't be raised or handled.

You should generally leave these signals alone unless you really understand how job control works. See Chapter 24 [Job Control], page 495.

int SIGCHLD Macro

This signal is sent to a parent process whenever one of its child processes terminates or stops.

The default action for this signal is to ignore it. If you establish a handler for this signal while there are child processes that have terminated but not reported their status via wait or waitpid (see Section 23.6 [Process Completion], page 488), whether your new handler applies to those processes or not depends on the particular operating system.

int SIGCONT Macro

You can send a SIGCONT signal to a process to make it continue. The default behavior for this signal is to make the process continue if it is stopped, and to ignore it otherwise.

Most programs have no reason to handle SIGCONT; they simply resume execution without realizing they were ever stopped. You can use a handler for SIGCONT to make a program do something special when it is stopped and continued—for example, to reprint a prompt when it is suspended while waiting for input.

int SIGSTOP Macro

The SIGSTOP signal stops the process. It cannot be handled, ignored, or blocked.

int SIGTSTP Macro

The SIGTSTP signal is an interactive stop signal. Unlike SIGSTOP, this signal can be handled and ignored.

Your program should handle this signal if you have a special need to leave files or system tables in a secure state when a process is stopped. For example, programs that turn off echoing should handle SIGTSTP so they can turn echoing back on before stopping.

This signal is generated when the user types the SUSP character (normally C-z). For more information about terminal driver support, see Section 16.4.9 [Special Characters], page 335.

int SIGTTIN Macro

A process cannot read from the user's terminal while it is running as a background job. When any process in a background job tries to read from the terminal, all of the processes in the job are sent a SIGTTIN signal. The default action for this signal is to stop the process. For more information about how this interacts with the terminal driver, see Section 24.4 [Access to the Terminal], page 497.

int SIGTTOU Macro

This is similar to SIGTTIN, but is generated when a process in a background job attempts to write to the terminal or set its modes. Again, the default action is to stop the process.

While a process is stopped, no more signals can be delivered to it until it is continued, except SIGKILL signals and (obviously) SIGCONT signals. The SIGKILL signal always causes termination of the process and can't be blocked or ignored. You can block or ignore SIGCONT, but it always causes the process to be continued anyway if it is stopped. Sending a SIGCONT signal to a process causes any pending stop signals for that process to be discarded. Likewise, any pending SIGCONT signals for a process are discarded when it receives a stop signal.

When a process in an orphaned process group (see Section 24.5 [Orphaned Process Groups], page 498) receives a SIGTSTP, SIGTTIN, or SIGTTOU signal and does not handle it, the process does not stop. Stopping the process would be unreasonable since there would be no way to continue

it. What happens instead depends on the operating system you are using. Some systems may do nothing; others may deliver another signal instead, such as SIGKILL or SIGHUP.

21.2.6 Miscellaneous Signals

These signals are used to report various other conditions. The default action for all of them is to cause the process to terminate.

int SIGPIPE Macro

If you use pipes or FIFOs, you have to design your application so that one process opens the pipe for reading before another starts writing. If the reading process never starts, or terminates unexpectedly, writing to the pipe or FIFO raises a SIGPIPE signal. If SIGPIPE is blocked, handled or ignored, the offending call fails with EPIPE instead.

Pipes and FIFO special files are discussed in more detail in Chapter 14 [Pipes and FIFOs], page 263.

Another cause of SIGPIPE is when you try to output to a socket that isn't connected. See Section 15.8.5.1 [Sending Data], page 300.

int SIGUSR1 Macro

int SIGUSR2 Macro

The SIGUSR1 and SIGUSR2 signals are set aside for you to use any way you want. They're useful for interprocess communication. Since these signals are normally fatal, you should write a signal handler for them in the program that receives the signal.

There is an example showing the use of SIGUSR1 and SIGUSR2 in Section 21.6.2 [Signaling Another Process], page 441.

21.2.7 Nonstandard Signals

Particular operating systems support additional signals not listed above. The ANSI C standard reserves all identifiers beginning with 'SIG' followed by an uppercase letter for the names of signals. You should consult the documentation or header files for your particular operating system and processor type to find out about the specific signals it supports.

For example, some systems support extra signals which correspond to hardware traps. Some other kinds of signals commonly supported are used to implement limits on CPU time or file system usage, asynchronous changes to terminal configuration, and the like. Systems may also define signal names that are aliases for standard signal names.

You can generally assume that the default action (or the action set up by the shell) for implementation-defined signals is reasonable, and not worry about them yourself. In fact, it's usually a bad idea to ignore or block signals you don't know anything about, or try to establish a handler for signals whose meanings you don't know.

Here are some of the other signals found on commonly used operating systems:

SIGCLD Obsolete name for SIGCHLD.

SIGTRAP Generated by the machine's breakpoint instruction. Used by debuggers. Default action is to dump core.

SIGIOT Generated by the PDP-11 "iot" instruction; equivalent to SIGABRT. Default action is to dump core.

SIGEMT Emulator trap; this results from certain unimplemented instructions. It is a program error signal.

SIGSYS Bad system call; that is to say, the instruction to trap to the operating system was executed, but the code number for the system call to perform was invalid. This is a program error signal.

SIGPOLL This is a System V signal name, more or less similar to SIGIO.

SIGXCPU CPU time limit exceeded. This is used for batch processing. Default action is program termination.

SIGXFSZ File size limit exceeded. This is used for batch processing. Default action is program termination.

SIGWINCH Window size change. This is generated on certain systems when the size of the current window on the screen is changed. Default action is to ignore it.

21.2.8 Signal Messages

We mentioned above that the shell prints a message describing the signal that terminated a child process. The clean way to print a message describing a signal is to use the functions strsignal and psignal. These functions use a signal number to specify which kind of signal to describe. The signal number may come from the termination status of a child process (see Section 23.6 [Process Completion], page 488) or it may come from a signal handler in the same process.

char * strsignal (int signum)

Function

This function returns a pointer to a statically-allocated string containing a message describing the signal *signum*. You should not modify the contents of this string; and, since it can be rewritten on subsequent calls, you should save a copy of it if you need to reference it later.

This function is a GNU extension, declared in the header file 'string.h'.

void psignal (int signum, const char *message)

Function

This function prints a message describing the signal signum to the standard error output stream stderr; see Section 11.2 [Standard Streams], page 139.

If you call psignal with a message that is either a null pointer or an empty string, psignal just prints the message corresponding to signum, adding a trailing newline.

If you supply a non-null message argument, then psignal prefixes its output with this string. It adds a colon and a space character to separate the message from the string corresponding to signum.

This function is a BSD feature, declared in the header file 'stdio.h'.

There is also an array sys_siglist which contains the messages for the various signal codes. This array exists on BSD systems, unlike strsignal.

21.3 Specifying Signal Actions

The simplest way to change the action for a signal is to use the **signal** function. You can specify a built-in action (such as to ignore the signal), or you can establish a handler.

The GNU library also implements the more versatile sigaction facility. This section describes both facilities and gives suggestions on which to use when.

21.3.1 Basic Signal Handling

The signal function provides a simple interface for establishing an action for a particular signal. The function and associated macros are declared in the header file 'signal.h'.

sighandler_t Data Type

This is the type of signal handler functions. Signal handlers take one integer argument specifying the signal number, and have return type void. So, you should define handler functions like this:

```
void handler (int signum) { ... }
```

The name sighandler_t for this data type is a GNU extension.

```
sighandler_t signal (int signum, sighandler_t action)
```

Function

The signal function establishes action as the action for the signal signum.

The first argument, signum, identifies the signal whose behavior you want to control, and should be a signal number. The proper way to specify a signal number is with one of the symbolic signal names described in Section 21.2 [Standard Signals], page 406—don't use an explicit number, because the numerical code for a given kind of signal may vary from operating system to operating system.

The second argument, action, specifies the action to use for the signal signum. This can be one of the following:

- SIG_DFL specifies the default action for the particular signal. The default actions for various kinds of signals are stated in Section 21.2 [Standard Signals], page 406.
- SIG_IGN SIG_IGN specifies that the signal should be ignored.

Your program generally should not ignore signals that represent serious events or that are normally used to request termination. You cannot ignore the SIGKILL or SIGSTOP signals at all. You can ignore program error signals like SIGSEGV, but ignoring the error won't enable the program to continue executing meaningfully. Ignoring user requests such as SIGINT, SIGQUIT, and SIGTSTP is unfriendly.

When you do not wish signals to be delivered during a certain part of the program, the thing to do is to block them, not ignore them. See Section 21.7 [Blocking Signals], page 445.

handler Supply the address of a handler function in your program, to specify running this handler as the way to deliver the signal.

For more information about defining signal handler functions, see Section 21.4 [Defining Handlers], page 425.

If you set the action for a signal to SIG_IGN, or if you set it to SIG_DFL and the default action is to ignore that signal, then any pending signals of that type are discarded (even if they are blocked). Discarding the pending signals means that they will never be delivered, not even if you subsequently specify another action and unblock this kind of signal.

The **signal** function returns the action that was previously in effect for the specified signum. You can save this value and restore it later by calling **signal** again.

If signal can't honor the request, it returns SIG_ERR instead. The following errno error conditions are defined for this function:

You specified an invalid *signum*; or you tried to ignore or provide a handler for SIGKILL or SIGSTOP.

Here is a simple example of setting up a handler to delete temporary files when certain fatal signals happen:

```
#include <signal.h>

void
termination_handler (int signum)
{
   struct temp_file *p;

   for (p = temp_file_list; p; p = p->next)
        unlink (p->name);
}

int
main (void)
```

```
...
if (signal (SIGINT, termination_handler) == SIG_IGN)
    signal (SIGINT, SIG_IGN);
if (signal (SIGHUP, termination_handler) == SIG_IGN)
    signal (SIGHUP, SIG_IGN);
if (signal (SIGTERM, termination_handler) == SIG_IGN)
    signal (SIGTERM, SIG_IGN);
...
}
```

Note how if a given signal was previously set to be ignored, this code avoids altering that setting. This is because non-job-control shells often ignore certain signals when starting children, and it is important for the children to respect this.

We do not handle SIGQUIT or the program error signals in this example because these are designed to provide information for debugging (a core dump), and the temporary files may give useful information.

```
sighandler_t ssignal (int signum, sighandler_t action)
```

Function

The ssignal function does the same thing as signal; it is provided only for compatibility with SVID.

sighandler_t SIG_ERR

Macro

The value of this macro is used as the return value from signal to indicate an error.

21.3.2 Advanced Signal Handling

The sigaction function has the same basic effect as signal: to specify how a signal should be handled by the process. However, sigaction offers more control, at the expense of more complexity. In particular, sigaction allows you to specify additional flags to control when the signal is generated and how the handler is invoked.

The sigaction function is declared in 'signal.h'.

The GNU C Library

struct sigaction Data Type

Structures of type struct sigaction are used in the sigaction function to specify all the information about how to handle a particular signal. This structure contains at least the following members:

sighandler_t sa_handler

This is used in the same way as the *action* argument to the signal function. The value can be SIG_DFL, SIG_IGN, or a function pointer. See Section 21.3.1 [Basic Signal Handling], page 416.

sigset_t sa_mask

This specifies a set of signals to be blocked while the handler runs. Blocking is explained in Section 21.7.5 [Blocking for Handler], page 450. Note that the signal that was delivered is automatically blocked by default before its handler is started; this is true regardless of the value in sa_mask. If you want that signal not to be blocked within its handler, you must write code in the handler to unblock it.

int sa_flags

This specifies various flags which can affect the behavior of the signal. These are described in more detail in Section 21.3.5 [Flags for Sigaction], page 423.

int sigaction (int signum, const struct sigaction *action, struct sigaction *old action)

The action argument is used to set up a new action for the signal signum, while the old_action argument is used to return information about the action previously associated with this symbol. (In other words, old_action has the same purpose as the signal function's return value—you can check to see what the old action in effect for the signal was, and restore it later if you want.)

Either action or old_action can be a null pointer. If old_action is a null pointer, this simply suppresses the return of information about the old action. If action is a null pointer, the action associated with the signal signum is unchanged; this allows you to inquire about how a signal is being handled without changing that handling.

The return value from sigaction is zero if it succeeds, and -1 on failure. The following error conditions are defined for this function:

EINVAL The *signum* argument is not valid, or you are trying to trap or ignore SIGKILL or SIGSTOP.

21.3.3 Interaction of signal and sigaction

It's possible to use both the **signal** and **sigaction** functions within a single program, but you have to be careful because they can interact in slightly strange ways.

The signation function specifies more information than the signal function, so the return value from signal cannot express the full range of signation possibilities. Therefore, if you use signal to save and later reestablish an action, it may not be able to reestablish properly a handler that was established with signation.

To avoid having problems as a result, always use sigaction to save and restore a handler if your program uses sigaction at all. Since sigaction is more general, it can properly save and reestablish any action, regardless of whether it was established originally with signal or sigaction.

If you establish an action with signal and then examine it with sigaction, the handler address that you get may not be the same as what you specified with signal. It may not even be suitable for use as an action argument with signal. But you can rely on using it as an argument to sigaction.

So, you're better off using one or the other of the mechanisms consistently within a single program.

Portability Note: The basic signal function is a feature of ANSI C, while sigaction is part of the POSIX.1 standard. If you are concerned about portability to non-POSIX systems, then you should use the signal function instead.

21.3.4 sigaction Function Example

In Section 21.3.1 [Basic Signal Handling], page 416, we gave an example of establishing a simple handler for termination signals using signal. Here is an equivalent example using sigaction:

#include <signal.h>

void

```
termination_handler (int signum)
  struct temp_file *p;
  for (p = temp_file_list; p; p = p->next)
    unlink (p->name);
}
int
main (void)
  struct sigaction new_action, old_action;
  /* Set up the structure to specify the new action. */
 new_action.sa_handler = termination_handler;
  sigemptyset (&new_action.sa_mask);
 new_action.sa_flags = 0;
  sigaction (SIGINT, NULL, &old_action);
  if (old_action.sa_handler != SIG_IGN)
    sigaction (SIGINT, &new_action, NULL);
  sigaction (SIGHUP, NULL, &old_action);
  if (old_action.sa_handler != SIG_IGN)
    sigaction (SIGHUP, &new_action, NULL);
  sigaction (SIGTERM, NULL, &old_action);
  if (old_action.sa_handler != SIG_IGN)
    sigaction (SIGTERM, &new_action, NULL);
}
```

The program just loads the new_action structure with the desired parameters and passes it in the sigaction call. The usage of sigemptyset is described later; see Section 21.7 [Blocking Signals], page 445.

As in the example using signal, we avoid handling signals previously set to be ignored. Here we can avoid altering the signal handler even momentarily, by using the feature of sigaction that lets us examine the current action without specifying a new one.

Here is another example. It retrieves information about the current action for SIGINT without changing that action.

```
struct sigaction query_action;
```

```
if (sigaction (SIGINT, NULL, &query_action) < 0)
   /* sigaction returns -1 in case of error. */
else if (query_action.sa_handler == SIG_DFL)
   /* SIGINT is handled in the default, fatal manner. */
else if (query_action.sa_handler == SIG_IGN)
   /* SIGINT is ignored. */
else
   /* A programmer-defined signal handler is in effect. */</pre>
```

21.3.5 Flags for sigaction

The sa_flags member of the sigaction structure is a catch-all for special features. Most of the time, SA_RESTART is a good value to use for this field.

The value of sa_flags is interpreted as a bit mask. Thus, you should choose the flags you want to set, OR those flags together, and store the result in the sa_flags member of your sigaction structure.

Each signal number has its own set of flags. Each call to sigaction affects one particular signal number, and the flags that you specify apply only to that particular signal.

In the GNU C library, establishing a handler with signal sets all the flags to zero except for SA_RESTART, whose value depends on the settings you have made with siginterrupt. See Section 21.5 [Interrupted Primitives], page 438, to see what this is about.

These macros are defined in the header file 'signal.h'.

int SA_NOCLDSTOP

Macro

This flag is meaningful only for the SIGCHLD signal. When the flag is set, the system delivers the signal for a terminated child process but not for one that is stopped. By default, SIGCHLD is delivered for both terminated children and stopped children.

Setting this flag for a signal other than SIGCHLD has no effect.

int SA_ONSTACK Macro

If this flag is set for a particular signal number, the system uses the signal stack when delivering that kind of signal. See Section 21.9 [BSD Signal Handling], page 458.

int SA_RESTART Macro

This flag controls what happens when a signal is delivered during certain primitives (such as open, read or write), and the signal handler returns normally. There are two alternatives: the library function can resume, or it can return failure with error code EINTR.

The choice is controlled by the SA_RESTART flag for the particular kind of signal that was delivered. If the flag is set, returning from a handler resumes the library function. If the flag is clear, returning from a handler makes the function fail. See Section 21.5 [Interrupted Primitives], page 438.

21.3.6 Initial Signal Actions

When a new process is created (see Section 23.4 [Creating a Process], page 483), it inherits handling of signals from its parent process. However, when you load a new process image using the exec function (see Section 23.5 [Executing a File], page 485), any signals that you've defined your own handlers for revert to their SIG_DFL handling. (If you think about it a little, this makes sense; the handler functions from the old program are specific to that program, and aren't even present in the address space of the new program image.) Of course, the new program can establish its own handlers.

When a program is run by a shell, the shell normally sets the initial actions for the child process to SIG_DFL or SIG_IGN, as appropriate. It's a good idea to check to make sure that the shell has not set up an initial action of SIG_IGN before you establish your own signal handlers.

Here is an example of how to establish a handler for SIGHUP, but not if SIGHUP is currently ignored:

```
struct sigaction temp;
sigaction (SIGHUP, NULL, &temp);
if (temp.sa_handler != SIG_IGN)
  {
   temp.sa_handler = handle_sighup;
   sigemptyset (&temp.sa_mask);
   sigaction (SIGHUP, &temp, NULL);
}
```

21.4 Defining Signal Handlers

This section describes how to write a signal handler function that can be established with the signal or sigaction functions.

A signal handler is just a function that you compile together with the rest of the program. Instead of directly invoking the function, you use **signal** or **sigaction** to tell the operating system to call it when a signal arrives. This is known as *establishing* the handler. See Section 21.3 [Signal Actions], page 416.

There are two basic strategies you can use in signal handler functions:

- You can have the handler function note that the signal arrived by tweaking some global data structures, and then return normally.
- You can have the handler function terminate the program or transfer control to a point where it can recover from the situation that caused the signal.

You need to take special care in writing handler functions because they can be called asynchronously. That is, a handler might be called at any point in the program, unpredictably. If two signals arrive during a very short interval, one handler can run within another. This section describes what your handler should do, and what you should avoid.

21.4.1 Signal Handlers That Return

Handlers which return normally are usually used for signals such as SIGALRM and the I/O and interprocess communication signals. But a handler for SIGINT might also return normally after setting a flag that tells the program to exit at a convenient time.

It is not safe to return normally from the handler for a program error signal, because the behavior of the program when the handler function returns is not defined after a program error. See Section 21.2.1 [Program Error Signals], page 406.

Handlers that return normally must modify some global variable in order to have any effect. Typically, the variable is one that is examined periodically by the program during normal operation. Its data type should be sig_atomic_t for reasons described in Section 21.4.7 [Atomic Data Access], page 436.

Here is a simple example of such a program. It executes the body of the loop until it has noticed that a SIGALRM signal has arrived. This technique is useful because it allows the iteration in progress when the signal arrives to complete before the loop exits.

```
#include <signal.h>
#include <stdio.h>
#include <stdlib.h>
/* This flag controls termination of the main loop. */
volatile sig_atomic_t keep_going = 1;
/* The signal handler just clears the flag and re-enables itself. */
void
catch_alarm (int sig)
 keep_going = 0;
  signal (sig, catch_alarm);
}
void
do_stuff (void)
 puts ("Doing stuff while waiting for alarm....");
}
int
main (void)
```

```
{
  /* Establish a handler for SIGALRM signals. */
  signal (SIGALRM, catch_alarm);

  /* Set an alarm to go off in a little while. */
  alarm (2);

  /* Check the flag once in a while to see when to quit. */
  while (keep_going)
    do_stuff ();

  return EXIT_SUCCESS;
}
```

21.4.2 Handlers That Terminate the Process

Handler functions that terminate the program are typically used to cause orderly cleanup or recovery from program error signals and interactive interrupts.

The cleanest way for a handler to terminate the process is to raise the same signal that ran the handler in the first place. Here is how to do this:

```
volatile sig_atomic_t fatal_error_in_progress = 0;
void
fatal_error_signal (int sig)
{
    /* Since this handler is established for more than one kind of signal,
        it might still get invoked recursively by delivery of some other kind
        of signal. Use a static variable to keep track of that. */
    if (fatal_error_in_progress)
        raise (sig);
    fatal_error_in_progress = 1;

/* Now do the clean up actions:
        - reset terminal modes
        - kill child processes
        - remove lock files */
...
```

```
/* Now reraise the signal. Since the signal is blocked,
   it will receive its default handling, which is
   to terminate the process. We could just call
   exit or abort, but reraising the signal
   sets the return status from the process correctly. */
   raise (sig);
}
```

21.4.3 Nonlocal Control Transfer in Handlers

You can do a nonlocal transfer of control out of a signal handler using the setjmp and longjmp facilities (see Chapter 20 [Non-Local Exits], page 397).

When the handler does a nonlocal control transfer, the part of the program that was running will not continue. If this part of the program was in the middle of updating an important data structure, the data structure will remain inconsistent. Since the program does not terminate, the inconsistency is likely to be noticed later on.

There are two ways to avoid this problem. One is to block the signal for the parts of the program that update important data structures. Blocking the signal delays its delivery until it is unblocked, once the critical updating is finished. See Section 21.7 [Blocking Signals], page 445.

The other way to re-initialize the crucial data structures in the signal handler, or make their values consistent.

Here is a rather schematic example showing the reinitialization of one global variable.

```
#include <signal.h>
#include <setjmp.h>
jmp_buf return_to_top_level;
volatile sig_atomic_t waiting_for_input;
void
handle_sigint (int signum)
  /* We may have been waiting for input when the signal arrived,
     but we are no longer waiting once we transfer control. */
  waiting_for_input = 0;
  longjmp (return_to_top_level, 1);
}
int
main (void)
{
  signal (SIGINT, sigint_handler);
  while (1) {
    prepare_for_command ();
    if (setjmp (return_to_top_level) == 0)
      read_and_execute_command ();
  }
}
```

```
/* Imagine this is a subroutine used by various commands. */
char *
read_data ()
{
   if (input_from_terminal) {
      waiting_for_input = 1;
      ...
      waiting_for_input = 0;
   } else {
      ...
}
```

21.4.4 Signals Arriving While a Handler Runs

What happens if another signal arrives when your signal handler function is running?

When the handler for a particular signal is invoked, that signal is normally blocked until the handler returns. That means that if two signals of the same kind arrive close together, the second one will be held until the first has been handled. (The handler can explicitly unblock the signal using sigprocmask, if you want to allow more signals of this type to arrive; see Section 21.7.3 [Process Signal Mask], page 448.)

However, your handler can still be interrupted by delivery of another kind of signal. To avoid this, you can use the sa_mask member of the action structure passed to sigaction to explicitly specify which signals should be blocked while the signal handler runs. These signals are in addition to the signal for which the handler was invoked, and any other signals that are normally blocked by the process. See Section 21.7.5 [Blocking for Handler], page 450.

Portability Note: Always use sigaction to establish a handler for a signal that you expect to receive asynchronously, if you want your program to work properly on System V Unix. On this system, the handling of a signal whose handler was established with signal automatically sets the signal's action back to SIG_DFL, and the handler must re-establish itself each time it runs. This practice, while inconvenient, does work when signals cannot arrive in succession. However, if another signal can arrive right away, it may arrive before the handler can re-establish itself. Then the second signal would receive the default handling, which could terminate the process.

21.4.5 Signals Close Together Merge into One

If multiple signals of the same type are delivered to your process before your signal handler has a chance to be invoked at all, the handler may only be invoked once, as if only a single signal had arrived. In effect, the signals merge into one. This situation can arise when the signal is blocked, or in a multiprocessing environment where the system is busy running some other processes while the signals are delivered. This means, for example, that you cannot reliably use a signal handler to count signals. The only distinction you can reliably make is whether at least one signal has arrived since a given time in the past.

Here is an example of a handler for SIGCHLD that compensates for the fact that the number of signals recieved may not equal the number of child processes generate them. It assumes that the program keeps track of all the child processes with a chain of structures as follows:

```
struct process
{
    struct process *next;
    /* The process ID of this child. */
    int pid;
    /* The descriptor of the pipe or pseudo terminal
        on which output comes from this child. */
    int input_descriptor;
    /* Nonzero if this process has stopped or terminated. */
    sig_atomic_t have_status;
    /* The status of this child; 0 if running,
        otherwise a status value from waitpid. */
    int status;
};
struct process *process_list;
```

This example also uses a flag to indicate whether signals have arrived since some time in the past—whenever the program last cleared it to zero.

```
/* Nonzero means some child's status has changed
    so look at process_list for the details. */
int process_status_change;
```

Here is the handler itself:

```
void
sigchld_handler (int signo)
  int old_errno = errno;
  while (1) {
    register int pid;
    int w;
    struct process *p;
    /* Keep asking for a status until we get a definitive result. */
    do
      {
         errno = 0;
        pid = waitpid (WAIT_ANY, &w, WNOHANG | WUNTRACED);
    while (pid <= 0 && errno == EINTR);</pre>
    if (pid <= 0) {
      /* A real failure means there are no more
         stopped or terminated child processes, so return. */
      errno = old_errno;
      return;
    }
    /* Find the process that signaled us, and record its status. */
    for (p = process_list; p; p = p->next)
      if (p->pid == pid) {
        p->status = w;
         /* Indicate that the status field
            has data to look at. We do this only after storing it. */
        p->have_status = 1;
        /* If process has terminated, stop waiting for its output. */
         if (WIFSIGNALED (w) || WIFEXITED (w))
           if (p->input_descriptor)
             FD_CLR (p->input_descriptor, &input_wait_mask);
         /* The program should check this flag from time to time
            to see if there is any news in process_list. */
         ++process_status_change;
    /* Loop around to handle all the processes
       that have something to tell us. */
  }
}
```

Here is the proper way to check the flag process_status_change:

It is vital to clear the flag before examining the list; otherwise, if a signal were delivered just before the clearing of the flag, and after the appropriate element of the process list had been checked, the status change would go unnoticed until the next signal arrived to set the flag again. You could, of course, avoid this problem by blocking the signal while scanning the list, but it is much more elegant to guarantee correctness by doing things in the right order.

The loop which checks process status avoids examining p->status until it sees that status has been validly stored. This is to make sure that the status cannot change in the middle of accessing it. Once p->have_status is set, it means that the child process is stopped or terminated, and in either case, it cannot stop or terminate again until the program has taken notice. See Section 21.4.7.3 [Atomic Usage], page 438, for more information about coping with interruptions during accessings of a variable.

Here is another way you can test whether the handler has run since the last time you checked. This technique uses a counter which is never changed outside the handler. Instead of clearing the count, the program remembers the previous value and sees whether it has changed since the previous check. The advantage of this method is that different parts of the program can check independently, each part checking whether there has been a signal since that part last checked.

```
sig_atomic_t process_status_change;
sig_atomic_t last_process_status_change;
...
```

21.4.6 Signal Handling and Nonreentrant Functions

Handler functions usually don't do very much. The best practice is to write a handler that does nothing but set an external variable that the program checks regularly, and leave all serious work to the program. This is best because the handler can be called at asynchronously, at unpredictable times—perhaps in the middle of a system call, or even between the beginning and the end of a C operator that requires multiple instructions. The data structures being manipulated might therefore be in an inconsistent state when the handler function is invoked. Even copying one int variable into another can take two instructions on most machines.

This means you have to be very careful about what you do in a signal handler.

- If your handler needs to access any global variables from your program, declare those variables volatile. This tells the compiler that the value of the variable might change asynchronously, and inhibits certain optimizations that would be invalidated by such modifications.
- If you call a function in the handler, make sure it is *reentrant* with respect to signals, or else make sure that the signal cannot interrupt a call to a related function.

A function can be non-reentrant if it uses memory that is not on the stack.

• If a function uses a static variable or a global variable, or a dynamically-allocated object that it finds for itself, then it is non-reentrant and any two calls to the function can interfere.

For example, suppose that the signal handler uses gethostbyname. This function returns its value in a static object, reusing the same object each time. If the signal happens to arrive during a call to gethostbyname, or even after one (while the program is still using the value), it will clobber the value that the program asked for.

However, if the program does not use gethostbyname or any other function that returns information in the same object, or if it always blocks signals around each use, then you are safe.

There are a large number of library functions that return values in a fixed object, always reusing the same object in this fashion, and all of them cause the same problem. The description of a function in this manual always mentions this behavior.

• If a function uses and modifies an object that you supply, then it is potentially non-reentrant; two calls can interfere if they use the same object.

This case arises when you do I/O using streams. Suppose that the signal handler prints a message with fprintf. Suppose that the program was in the middle of an fprintf call using the same stream when the signal was delivered. Both the signal handler's message and the program's data could be corrupted, because both calls operate on the same data structure—the stream itself.

However, if you know that the stream that the handler uses cannot possibly be used by the program at a time when signals can arrive, then you are safe. It is no problem if the program uses some other stream.

• On most systems, malloc and free are not reentrant, because they use a static data structure which records what memory blocks are free. As a result, no library functions that allocate or free memory are reentrant. This includes functions that allocate space to store a result.

The best way to avoid the need to allocate memory in a handler is to allocate in advance space for signal handlers to use.

The best way to avoid freeing memory in a handler is to flag or record the objects to be freed, and have the program check from time to time whether anything is waiting to be freed. But this must be done with care, because placing an object on a chain is not atomic, and if it is interrupted by another signal handler that does the same thing, you could "lose" one of the objects.

On the GNU system, malloc and free are safe to use in signal handlers because it blocks signals. As a result, the library functions that allocate space for a result are also safe in signal handlers. The obstack allocation functions are safe as long as you don't use the same obstack both inside and outside of a signal handler.

The relocating allocation functions (see Section 3.6 [Relocating Allocator], page 57) are certainly not safe to use in a signal handler.

• Any function that modifies errno is non-reentrant, but you can correct for this: in the handler, save the original value of errno and restore it before returning normally. This prevents errors that occur within the signal handler from being confused with errors from system calls at the point the program is interrupted to run the handler.

This technique is generally applicable; if you want to call in a handler a function that modifies a particular object in memory, you can make this safe by saving and restoring that object.

- Merely reading from a memory object is safe provided that you can deal with any of the values that might appear in the object at a time when the signal can be delivered. Keep in mind that assignment to some data types requires more than one instruction, which means that the handler could run "in the middle of" an assignment to the variable if its type is not atomic. See Section 21.4.7 [Atomic Data Access], page 436.
- Merely writing into a memory object is safe as long as a sudden change in the value, at any time when the handler might run, will not disturb anything.

21.4.7 Atomic Data Access and Signal Handling

Whether the data in your application concerns atoms, or mere text, you have to be careful about the fact that access to a single datum is not necessarily *atomic*. This means that it can take more than one instruction to read or write a single object. In such cases, a signal handler can run in the middle of reading or writing the object.

There are three ways you can cope with this problem. You can use data types that are always accessed atomically; you can carefully arrange that nothing untoward happens if an access is interrupted, or you can block all signals around any access that had better not be interrupted (see Section 21.7 [Blocking Signals], page 445).

21.4.7.1 Example of Problems with Non-Atomic Access

Here is an example which shows what can happen if a signal handler runs in the middle of modifying a variable. (Interrupting the reading of a variable can also lead to paradoxical results, but here we only show writing.)

```
#include <signal.h>
#include <stdio.h>

struct two_words { int a, b; } memory;

void
handler(int signum)
{
    printf ("%d,%d\n", memory.a, memory.b);
    alarm (1);
}
```

```
int
main (void)
{
    static struct two_words zeros = { 0, 0 }, ones = { 1, 1 };
    signal (SIGALRM, handler);
    memory = zeros;
    alarm (1);
    while (1)
      {
         memory = zeros;
         memory = ones;
    }
}
```

This program fills memory with zeros, ones, zeros, ones, alternating forever; meanwhile, once per second, the alarm signal handler prints the current contents. (Calling printf in the handler is safe in this program because it is certainly not being called outside the handler when the signal happens.)

Clearly, this program can print a pair of zeros or a pair of ones. But that's not all it can do! On most machines, it takes several instructions to store a new value in memory, and the value is stored one word at a time. If the signal is delivered in between these instructions, the handler might find that memory.a is zero and memory.b is one (or vice versa).

On some machines it may be possible to store a new value in memory with just one instruction that cannot be interrupted. On these machines, the handler will always print two zeros or two ones.

21.4.7.2 Atomic Types

To avoid uncertainty about interrupting access to a variable, you can use a particular data type for which access is always atomic: sig_atomic_t. Reading and writing this data type is guaranteed to happen in a single instruction, so there's no way for a handler to run "in the middle" of an access.

The type sig_atomic_t is always an integer data type, but which one it is, and how many bits it contains, may vary from machine to machine.

The GNU C Library

sig_atomic_t Data Type

This is an integer data type. Objects of this type are always accessed atomically.

In practice, you can assume that int and other integer types no longer than int are atomic. You can also assume that pointer types are atomic; that is very convenient. Both of these are true on all of the machines that the GNU C library supports, and on all POSIX systems we know of.

21.4.7.3 Atomic Usage Patterns

Certain patterns of access avoid any problem even if an access is interrupted. For example, a flag which is set by the handler, and tested and cleared by the main program from time to time, is always safe even if access actually requires two instructions. To show that this is so, we must consider each access that could be interrupted, and show that there is no problem if it is interrupted.

An interrupt in the middle of testing the flag is safe because either it's recognized to be nonzero, in which case the precise value doesn't matter, or it will be seen to be nonzero the next time it's tested.

An interrupt in the middle of clearing the flag is no problem because either the value ends up zero, which is what happens if a signal comes in just before the flag is cleared, or the value ends up nonzero, and subsequent events occur as if the signal had come in just after the flag was cleared. As long as the code handles both of these cases properly, it can also handle a signal in the middle of clearing the flag. (This is an example of the sort of reasoning you need to do to figure out whether non-atomic usage is safe.)

Sometimes you can insure uninterrupted access to one object by protecting its use with another object, perhaps one whose type guarantees atomicity. See Section 21.4.5 [Merged Signals], page 431, for an example.

21.5 Primitives Interrupted by Signals

A signal can arrive and be handled while an I/O primitive such as open or read is waiting for an I/O device. If the signal handler returns, the system faces the question: what should happen next?

POSIX specifies one approach: make the primitive fail right away. The error code for this kind of failure is EINTR. This is flexible, but usually inconvenient. Typically, POSIX applications that use signal handlers must check for EINTR after each library function that can return it, in order to try the call again. Often programmers forget to check, which is a common source of error.

The GNU library provides a convenient way to retry a call after a temporary failure, with the macro TEMP_FAILURE_RETRY:

TEMP_FAILURE_RETRY (expression)

Macro

This macro evaluates expression once. If it fails and reports error code EINTR, TEMP_FAILURE_RETRY evaluates it again, and over and over until the result is not a temporary failure.

The value returned by TEMP_FAILURE_RETRY is whatever value expression produced.

BSD avoids EINTR entirely and provides a more convenient approach: to restart the interrupted primitive, instead of making it fail. If you choose this approach, you need not be concerned with EINTR.

You can choose either approach with the GNU library. If you use signation to establish a signal handler, you can specify how that handler should behave. If you specify the SA_RESTART flag, return from that handler will resume a primitive; otherwise, return from that handler will cause EINTR. See Section 21.3.5 [Flags for Sigaction], page 423.

Another way to specify the choice is with the siginterrupt function. See Section 21.9.1 [POSIX vs BSD], page 458.

When you don't specify with sigaction or siginterrupt what a particular handler should do, it uses a default choice. The default choice in the GNU library depends on the feature test macros you have defined. If you define _BSD_SOURCE or _GNU_SOURCE before calling signal, the default is to resume primitives; otherwise, the default is to make them fail with EINTR. (The library contains alternate versions of the signal function, and the feature test macros determine which one you really call.) See Section 1.3.4 [Feature Test Macros], page 9.

The primitives affected by this issue are close, fcntl (operation F_SETLK), open, read, recv, recvfrom, select, send, sendto, tcdrain, waitpid, wait, and write.

440 The GNU C Library

There is one situation where resumption never happens no matter which choice you make: when a data-transfer function such as **read** or **write** is interrupted by a signal after transferring part of the data. In this case, the function returns the number of bytes already transferred, indicating partial success.

This might at first appear to cause unreliable behavior on record-oriented devices (including datagram sockets; see Section 15.9 [Datagrams], page 309), where splitting one read or write into two would read or write two records. Actually, there is no problem, because interruption after a partial transfer cannot happen on such devices; they always transfer an entire record in one burst, with no waiting once data transfer has started.

21.6 Generating Signals

Besides signals that are generated as a result of a hardware trap or interrupt, your program can explicitly send signals to itself or to another process.

21.6.1 Signaling Yourself

A process can send itself a signal with the raise function. This function is declared in 'signal.h'.

int raise (int signum)

Function

The raise function sends the signal signum to the calling process. It returns zero if successful and a nonzero value if it fails. About the only reason for failure would be if the value of signum is invalid.

int gsignal (int signum)

Function

The gsignal function does the same thing as raise; it is provided only for compatibility with SVID.

One convenient use for raise is to reproduce the default behavior of a signal that you have trapped. For instance, suppose a user of your program types the SUSP character (usually C-z; see Section 16.4.9 [Special Characters], page 335) to send it an interactive stop stop signal (SIGTSTP), and you want to clean up some internal data buffers before stopping. You might set this up like this:

```
#include <signal.h>
/* When a stop signal arrives, set the action back to the default
  and then resend the signal after doing cleanup actions. */
void
tstp_handler (int sig)
  signal (SIGTSTP, SIG_DFL);
  /* Do cleanup actions here. */
  raise (SIGTSTP);
/* When the process is continued again, restore the signal handler. */
void
cont_handler (int sig)
  signal (SIGCONT, cont_handler);
  signal (SIGTSTP, tstp_handler);
}
/* Enable both handlers during program initialization. */
int
main (void)
  signal (SIGCONT, cont_handler);
  signal (SIGTSTP, tstp_handler);
}
```

Portability note: raise was invented by the ANSI C committee. Older systems may not support it, so using kill may be more portable. See Section 21.6.2 [Signaling Another Process], page 441.

21.6.2 Signaling Another Process

The kill function can be used to send a signal to another process. In spite of its name, it can be used for a lot of things other than causing a process to terminate. Some examples of situations where you might want to send signals between processes are:

- A parent process starts a child to perform a task—perhaps having the child running an infinite loop—and then terminates the child when the task is no longer needed.
- A process executes as part of a group, and needs to terminate or notify the other processes in the group when an error or other event occurs.
- Two processes need to synchronize while working together.

This section assumes that you know a little bit about how processes work. For more information on this subject, see Chapter 23 [Child Processes], page 481.

The kill function is declared in 'signal.h'.

int kill (pid_t pid, int signum)

Function

The kill function sends the signal signum to the process or process group specified by pid. Besides the signals listed in Section 21.2 [Standard Signals], page 406, signum can also have a value of zero to check the validity of the pid.

The pid specifies the process or process group to receive the signal:

- pid > 0 The process whose identifier is pid.
- pid == 0 All processes in the same process group as the sender. The sender itself does not receive the signal.
- pid < -1 The process group whose identifier is -pid.
- pid == -1 If the process is privileged, send the signal to all processes except for some special system processes. Otherwise, send the signal to all processes with the same effective user ID.

A process can send a signal to itself with kill (getpid(), signum);. If kill is used by a process to send a signal to itself, and the signal is not blocked, then kill delivers at least one signal (which might be some other pending unblocked signal instead of the signal signum) to that process before it returns.

The return value from kill is zero if the signal can be sent successfully. Otherwise, no signal is sent, and a value of -1 is returned. If *pid* specifies sending a signal to several processes, kill succeeds if it can send the signal to at least one of them. There's no way you can tell which of the processes got the signal or whether all of them did.

The following errno error conditions are defined for this function:

EINVAL The signum argument is an invalid or unsupported number.

EPERM You do not have the privilege to send a signal to the process or any of the

processes in the process group named by pid.

ESCRH The pid argument does not refer to an existing process or group.

int killpg (int pgid, int signum)

Function

This is similar to kill, but sends signal signum to the process group pgid. This function is provided for compatibility with BSD; using kill to do this is more portable.

As a simple example of kill, the call kill (getpid (), sig) has the same effect as raise (sig).

21.6.3 Permission for using kill

There are restrictions that prevent you from using kill to send signals to any random process. These are intended to prevent antisocial behavior such as arbitrarily killing off processes belonging to another user. In typical use, kill is used to pass signals between parent, child, and sibling processes, and in these situations you normally do have permission to send signals. The only common execption is when you run a setuid program in a child process; if the program changes its real UID as well as its effective UID, you may not have permission to send a signal. The su program does this.

Whether a process has permission to send a signal to another process is determined by the user IDs of the two processes. This concept is discussed in detail in Section 25.2 [Process Persona], page 521.

Generally, for a process to be able to send a signal to another process, either the sending process must belong to a privileged user (like 'root'), or the real or effective user ID of the sending process must match the real or effective user ID of the receiving process. If the receiving process has changed its effective user ID from the set-user-ID mode bit on its process image file, then the owner of the process image file is used in place of its current effective user ID. In some implementations, a parent process might be able to send signals to a child process even if the user ID's don't match, and other implementations might enforce other restrictions.

The SIGCONT signal is a special case. It can be sent if the sender is part of the same session as the receiver, regardless of user IDs.

21.6.4 Using kill for Communication

Here is a longer example showing how signals can be used for interprocess communication. This is what the SIGUSR1 and SIGUSR2 signals are provided for. Since these signals are fatal by default, the process that is supposed to receive them must trap them through signal or signation.

In this example, a parent process forks a child process and then waits for the child to complete its initialization. The child process tells the parent when it is ready by sending it a SIGUSR1 signal, using the kill function.

```
#include <signal.h>
#include <stdio.h>
#include <sys/types.h>
#include <unistd.h>
/* When a SIGUSR1 signal arrives, set this variable.
volatile sig_atomic_t usr_interrupt = 0;
void
synch_signal (int sig)
  usr_interrupt = 1;
}
/* The child process executes this function. */
child_function (void)
{
  /* Perform initialization. */
 printf ("I'm here!!! My pid is %d.\n", (int) getpid ());
  /* Let parent know you're done. */
 kill (getppid (), SIGUSR1);
  /* Continue with execution. */
 puts ("Bye, now....");
  exit (0);
}
int
main (void)
```

```
{
  struct sigaction usr_action;
  sigset_t block_mask;
 pid_t child_id;
  /* Establish the signal handler. */
  sigfillset (&block_mask);
 usr_action.sa_handler = synch_signal;
  usr_action.sa_mask = block_mask;
  usr_action.sa_flags = 0;
  sigaction (SIGUSR1, &usr_action, NULL);
  /* Create the child process. */
  child_id = fork ();
  if (child_id == 0)
    child_function (); /* Does not return. */
  /* Busy wait for the child to send a signal. */
 while (!usr_interrupt)
  /* Now continue execution. */
 puts ("That's all, folks!");
  return 0;
}
```

This example uses a busy wait, which is bad, because it wastes CPU cycles that other programs could otherwise use. It is better to ask the system to wait until the signal arrives. See the example in Section 21.8 [Waiting for a Signal], page 454.

21.7 Blocking Signals

Blocking a signal means telling the operating system to hold it and deliver it later. Generally, a program does not block signals indefinitely—it might as well ignore them by setting their actions to SIG_IGN. But it is useful to block signals briefly, to prevent them from interrupting sensitive operations. For instance:

• You can use the sigprocmask function to block signals while you modify global variables that are also modified by the handlers for these signals.

• You can set sa_mask in your sigaction call to block certain signals while a particular signal handler runs. This way, the signal handler can run without being interrupted itself by signals.

21.7.1 Why Blocking Signals is Useful

446

Temporary blocking of signals with sigprocmask gives you a way to prevent interrupts during critical parts of your code. If signals arrive in that part of the program, they are delivered later, after you unblock them.

One example where this is useful is for sharing data between a signal handler and the rest of the program. If the type of the data is not sig_atomic_t (see Section 21.4.7 [Atomic Data Access], page 436), then the signal handler could run when the rest of the program has only half finished reading or writing the data. This would lead to confusing consequences.

To make the program reliable, you can prevent the signal handler from running while the rest of the program is examining or modifying that data—by blocking the appropriate signal around the parts of the program that touch the data.

Blocking signals is also necessary when you want to perform a certain action only if a signal has not arrived. Suppose that the handler for the signal sets a flag of type sig_atomic_t; you would like to test the flag and perform the action if the flag is not set. This is unreliable. Suppose the signal is delivered immediately after you test the flag, but before the consequent action: then the program will perform the action even though the signal has arrived.

The only way to test reliably for whether a signal has yet arrived is to test while the signal is blocked.

21.7.2 Signal Sets

All of the signal blocking functions use a data structure called a *signal set* to specify what signals are affected. Thus, every activity involves two stages: creating the signal set, and then passing it as an argument to a library function.

These facilities are declared in the header file 'signal.h'.

sigset_t Data Type

The sigset_t data type is used to represent a signal set. Internally, it may be implemented as either an integer or structure type.

For portability, use only the functions described in this section to initialize, change, and retrieve information from sigset_t objects—don't try to manipulate them directly.

There are two ways to initialize a signal set. You can initially specify it to be empty with sigemptyset and then add specified signals individually. Or you can specify it to be full with sigfillset and then delete specified signals individually.

You must always initialize the signal set with one of these two functions before using it in any other way. Don't try to set all the signals explicitly because the sigset_t object might include some other information (like a version field) that needs to be initialized as well. (In addition, it's not wise to put into your program an assumption that the system has no signals aside from the ones you know about.)

int sigemptyset (sigset_t *set)

Function

This function initializes the signal set set to exclude all of the defined signals. It always returns 0.

int sigfillset (sigset_t *set)

Function

This function initializes the signal set set to include all of the defined signals. Again, the return value is 0.

int sigaddset (sigset_t *set, int signum)

Function

This function adds the signal signum to the signal set set. All sigaddset does is modify set; it does not block or unblock any signals.

The return value is 0 on success and -1 on failure. The following errno error condition is defined for this function:

EINVAL The signum argument doesn't specify a valid signal.

int sigdelset (sigset_t *set, int signum)

Function

This function removes the signal signum from the signal set set. All sigdelset does is modify set; it does not block or unblock any signals. The return value and error conditions are the same as for sigaddset.

Finally, there is a function to test what signals are in a signal set:

int sigismember (const sigset_t *set, int signum)

Function

The **sigismember** function tests whether the signal *signum* is a member of the signal set *set*. It returns 1 if the signal is in the set, 0 if not, and -1 if there is an error.

The following errno error condition is defined for this function:

EINVAL The signum argument doesn't specify a valid signal.

21.7.3 Process Signal Mask

The collection of signals that are currently blocked is called the *signal mask*. Each process has its own signal mask. When you create a new process (see Section 23.4 [Creating a Process], page 483), it inherits its parent's mask. You can block or unblock signals with total flexibility by modifying the signal mask.

The prototype for the sigprocmask function is in 'signal.h'.

int sigprocmask (int how, const sigset_t *set, sigset_t *oldset)

Function

The sigprocmask function is used to examine or change the calling process's signal mask. The *how* argument determines how the signal mask is changed, and must be one of the following values:

SIG_BLOCK

Block the signals in **set**—add them to the existing mask. In other words, the new mask is the union of the existing mask and set.

SIG_UNBLOCK

Unblock the signals in set—remove them from the existing mask.

SIG_SETMASK

Use set for the mask; ignore the previous value of the mask.

The last argument, oldset, is used to return information about the old process signal mask. If you just want to change the mask without looking at it, pass a null pointer as the oldset argument. Similarly, if you want to know what's in the mask without changing it, pass a null pointer for set (in this case the how argument is not significant). The oldset argument is often used to remember the previous signal mask in order to restore it later. (Since the signal mask is inherited over fork and exec calls, you can't predict what its contents are when your program starts running.)

If invoking sigprocmask causes any pending signals to be unblocked, at least one of those signals is delivered to the process before sigprocmask returns. The order in which pending signals are delivered is not specified, but you can control the order explicitly by making multiple sigprockmask calls to unblock various signals one at a time.

The sigprocmask function returns 0 if successful, and -1 to indicate an error. The following error conditions are defined for this function:

EINVAL The how argument is invalid.

You can't block the SIGKILL and SIGSTOP signals, but if the signal set includes these, sigprocmask just ignores them instead of returning an error status.

Remember, too, that blocking program error signals such as SIGFPE leads to undesirable results for signals generated by an actual program error (as opposed to signals sent with raise or kill). This is because your program may be too broken to be able to continue executing to a point where the signal is unblocked again. See Section 21.2.1 [Program Error Signals], page 406.

21.7.4 Blocking to Test for Delivery of a Signal

Now for a simple example. Suppose you establish a handler for SIGALRM signals that sets a flag whenever a signal arrives, and your main program checks this flag from time to time and then resets it. You can prevent additional SIGALRM signals from arriving in the meantime by wrapping the critical part of the code with calls to sigprocmask, like this:

```
/* This variable is set by the SIGALRM signal handler. */
volatile sig_atomic_t flag = 0;
```

```
int
main (void)
  sigset_t block_alarm;
  /* Initialize the signal mask. */
  sigemptyset (&block_alarm);
  sigaddset (&block_alarm, SIGALRM);
  while (1)
    {
      /* Check if a signal has arrived; if so, reset the flag. */
      sigprocmask (SIG_BLOCK, &block_alarm, NULL);
      if (flag)
         {
           actions-if-not-arrived
           flag = 0;
         }
      sigprocmask (SIG_UNBLOCK, &block_alarm, NULL);
    }
}
```

21.7.5 Blocking Signals for a Handler

When a signal handler is invoked, you usually want it to be able to finish without being interrupted by another signal. From the moment the handler starts until the moment it finishes, you must block signals that might confuse it or corrupt its data.

When a handler function is invoked on a signal, that signal is automatically blocked (in addition to any other signals that are already in the process's signal mask) during the time the handler is running. If you set up a handler for SIGTSTP, for instance, then the arrival of that signal forces further SIGTSTP signals to wait during the execution of the handler.

However, by default, other kinds of signals are not blocked; they can arrive during handler execution.

The reliable way to block other kinds of signals during the execution of the handler is to use the sa_mask member of the sigaction structure.

Here is an example:

```
#include <signal.h>
#include <stddef.h>
void catch_stop ();
void
install_handler (void)
  struct sigaction setup_action;
  sigset_t block_mask;
  sigemptyset (&block_mask);
  /* Block other terminal-generated signals while handler runs. */
  sigaddset (&block_mask, SIGINT);
  sigaddset (&block_mask, SIGQUIT);
  setup_action.sa_handler = catch_stop;
  setup_action.sa_mask = block_mask;
  setup_action.sa_flags = 0;
  sigaction (SIGTSTP, &setup_action, NULL);
}
```

This is more reliable than blocking the other signals explicitly in the code for the handler. If you block signals explicity in the handler, you can't avoid at least a short interval at the beginning of the handler where they are not yet blocked.

You cannot remove signals from the process's current mask using this mechanism. However, you can make calls to sigprocmask within your handler to block or unblock signals as you wish.

In any case, when the handler returns, the system restores the mask that was in place before the handler was entered.

21.7.6 Checking for Pending Signals

You can find out which signals are pending at any time by calling sigpending. This function is declared in 'signal.h'.

```
int sigpending (sigset_t *set)
```

Function

The sigpending function stores information about pending signals in set. If there is a pending signal that is blocked from delivery, then that signal is a member of the returned set. (You can test whether a particular signal is a member of this set using sigismember; see Section 21.7.2 [Signal Sets], page 446.)

The return value is 0 if successful, and -1 on failure.

Testing whether a signal is pending is not often useful. Testing when that signal is not blocked is almost certainly bad design.

Here is an example.

```
#include <signal.h>
#include <stddef.h>

sigset_t base_mask, waiting_mask;

sigemptyset (&base_mask);
sigaddset (&base_mask, SIGINT);
sigaddset (&base_mask, SIGTSTP);

/* Block user interrupts while doing other processing. */
sigprocmask (SIG_SETMASK, &base_mask, NULL);
...

/* After a while, check to see whether any signals are pending. */
sigpending (&waiting_mask);
if (sigismember (&waiting_mask, SIGINT)) {
    /* User has tried to kill the process. */
}
else if (sigismember (&waiting_mask, SIGTSTP)) {
    /* User has tried to stop the process. */
}
```

Remember that if there is a particular signal pending for your process, additional signals of that same type that arrive in the meantime might be discarded. For example, if a SIGINT signal is pending when another SIGINT signal arrives, your program will probably only see one of them when you unblock this signal.

Portability Note: The **sigpending** function is new in POSIX.1. Older systems have no equivalent facility.

21.7.7 Remembering a Signal to Act On Later

Instead of blocking a signal using the library facilities, you can get almost the same results by making the handler set a flag to be tested later, when you "unblock". Here is an example:

```
/* If this flag is nonzero, don't handle the signal right away. */
volatile sig_atomic_t signal_pending;
/* This is nonzero if a signal arrived and was not handled. */
volatile sig_atomic_t defer_signal;
void
handler (int signum)
  if (defer_signal)
    signal_pending = signum;
  else
    ... /* "Really" handle the signal. */
}
void
update_mumble (int frob)
  /* Prevent signals from having immediate effect. */
  defer_signal++;
  /* Now update mumble, without worrying about interruption. */
  mumble.a = 1;
  mumble.b = hack ();
  mumble.c = frob;
  /* We have updated mumble. Handle any signal that came in. */
  defer_signal--;
  if (defer_signal == 0 && signal_pending != 0)
    raise (signal_pending);
}
```

Note how the particular signal that arrives is stored in signal_pending. That way, we can handle several types of inconvenient signals with the same mechanism.

We increment and decrement defer_signal so that nested critical sections will work properly; thus, if update_mumble were called with signal_pending already nonzero, signals would be deferred not only within update_mumble, but also within the caller. This is also why we do not check signal_pending if defer_signal is still nonzero.

The incrementing and decrementing of defer_signal require more than one instruction; it is possible for a signal to happen in the middle. But that does not cause any problem. If the signal happens early enough to see the value from before the increment or decrement, that is equivalent to a signal which came before the beginning of the increment or decrement, which is a case that works properly.

It is absolutely vital to decrement defer_signal before testing signal_pending, because this avoids a subtle bug. If we did these things in the other order, like this,

```
if (defer_signal == 1 && signal_pending != 0)
  raise (signal_pending);
defer_signal--;
```

then a signal arriving in between the if statement and the decrement would be effetively "lost" for an indefinite amount of time. The handler would merely set defer_signal, but the program having already tested this variable, it would not test the variable again.

Bugs like these are called *timing errors*. They are especially bad because they happen only rarely and are nearly impossible to reproduce. You can't expect to find them with a debugger as you would find a reproducible bug. So it is worth being especially careful to avoid them.

(You would not be tempted to write the code in this order, given the use of defer_signal as a counter which must be tested along with signal_pending. After all, testing for zero is cleaner than testing for one. But if you did not use defer_signal as a counter, and gave it values of zero and one only, then either order might seem equally simple. This is a further advantage of using a counter for defer_signal: it will reduce the chance you will write the code in the wrong order and create a subtle bug.)

21.8 Waiting for a Signal

If your program is driven by external events, or uses signals for synchronization, then when it has nothing to do it should probably wait until a signal arrives.

21.8.1 Using pause

The simple way to wait until a signal arrives is to call pause. Please read about its disadvantages, in the following section, before you use it.

int pause () Function

The pause function suspends program execution until a signal arrives whose action is either to execute a handler function, or to terminate the process.

If the signal causes a handler function to be executed, then pause returns. This is considered an unsuccessful return (since "successful" behavior would be to suspend the program forever), so the return value is -1. Even if you specify that other primitives should resume when a system handler returns (see Section 21.5 [Interrupted Primitives], page 438), this has no effect on pause; it always fails when a signal is handled.

The following errno error conditions are defined for this function:

EINTR The function was interrupted by delivery of a signal.

If the signal causes program termination, pause doesn't return (obviously).

The pause function is declared in 'unistd.h'.

21.8.2 Problems with pause

The simplicity of pause can conceal serious timing errors that can make a program hang mysteriously.

It is safe to use pause if the real work of your program is done by the signal handlers themselves, and the "main program" does nothing but call pause. Each time a signal is delivered, the handler will do the next batch of work that is to be done, and then return, so that the main loop of the program can call pause again.

You can't safely use pause to wait until one more signal arrives, and then resume real work. Even if you arrange for the signal handler to cooperate by setting a flag, you still can't use pause reliably. Here is an example of this problem:

```
/* usr_interrupt is set by the signal handler. */
if (!usr_interrupt)
   pause ();
/* Do work once the signal arrives. */
...
```

This has a bug: the signal could arrive after the variable usr_interrupt is checked, but before the call to pause. If no further signals arrive, the process would never wake up again.

You can put an upper limit on the excess waiting by using sleep in a loop, instead of using pause. (See Section 19.4 [Sleeping], page 390, for more about sleep.) Here is what this looks like:

```
/* usr_interrupt is set by the signal handler.
while (!usr_interrupt)
    sleep (1);
/* Do work once the signal arrives. */
...
```

For some purposes, that is good enough. But with a little more complexity, you can wait reliably until a particular signal handler is run, using sigsuspend.

21.8.3 Using sigsuspend

The clean and reliable way to wait for a signal to arrive is to block it and then use **sigsuspend**. By using **sigsuspend** in a loop, you can wait for certain kinds of signals, while letting other kinds of signals be handled by their handlers.

int sigsuspend (const sigset_t *set)

Function

This function replaces the process's signal mask with set and then suspends the process until a signal is delivered whose action is either to terminate the process or invoke a signal handling function. In other words, the program is effectively suspended until one of the signals that is not a member of set arrives.

If the process is woken up by deliver of a signal that invokes a handler function, and the handler function returns, then sigsuspend also returns.

The mask remains set only as long as sigsuspend is waiting. The function sigsuspend always restores the previous signal mask when it returns.

The return value and error conditions are the same as for pause.

With sigsuspend, you can replace the pause or sleep loop in the previous section with something completely reliable:

```
sigset_t mask, oldmask;
....
/* Set up the mask of signals to temporarily block. */
sigemptyset (&mask);
sigaddset (&mask, SIGUSR1);
...
/* Wait for a signal to arrive. */
sigprocmask (SIG_BLOCK, &mask, &oldmask);
while (!usr_interrupt)
   sigsuspend (&oldmask);
sigprocmask (SIG_UNBLOCK, &mask, NULL);
```

This last piece of code is a little tricky. The key point to remember here is that when sigsuspend returns, it resets the process's signal mask to the original value, the value from before the call to sigsuspend—in this case, the SIGUSR1 signal is once again blocked. The second call to sigprocmask is necessary to explicitly unblock this signal.

One other point: you may be wondering why the while loop is necessary at all, since the program is apparently only waiting for one SIGUSR1 signal. The answer is that the mask passed to sigsuspend permits the process to be woken up by the delivery of other kinds of signals, as well—for example, job control signals. If the process is woken up by a signal that doesn't set usr_interrupt, it just suspends itself again until the "right" kind of signal eventually arrives.

This technique takes a few more lines of preparation, but that is needed just once for each kind of wait criterion you want to use. The code that actually waits is just four lines.

21.9 BSD Signal Handling

This section describes alternative signal handling functions derived from BSD Unix. These facilities were an advance, in their time; today, they are mostly obsolete, and supported mainly for compatibility with BSD Unix.

They do provide one feature that is not available through the POSIX functions: You can specify a separate stack for use in certain signal handlers. Using a signal stack is the only way you can handle a signal caused by stack overflow.

21.9.1 POSIX and BSD Signal Facilities

There are many similarities between the BSD and POSIX signal handling facilities, because the POSIX facilities were inspired by the BSD facilities. Besides having different names for all the functions to avoid conflicts, the main differences between the two are:

- BSD Unix represents signal masks as an int bit mask, rather than as a sigset_t object.
- The BSD facilities use a different default for whether an interrupted primitive should fail or resume. The POSIX facilities make system calls fail unless you specify that they should resume. With the BSD facility, the default is to make system calls resume unless you say they should fail. See Section 21.5 [Interrupted Primitives], page 438.
- BSD Unix has a concept of a *signal stack*. This is an alternate stack that is used during the execution of signal handler functions, instead of its normal execution stack.

The BSD facilities are declared in 'signal.h'.

21.10 BSD Function to Establish a Handler

struct sigvec Data Type

This data type is the BSD equivalent of struct sigaction (see Section 21.3.2 [Advanced Signal Handling], page 419); it is used to specify signal actions to the sigvec function. It contains the following members:

sighandler_t sv_handler

This is the handler function.

int sv_mask

This is the mask of additional signals to be blocked while the handler function is being called.

int sv_flags

This is a bit mask used to specify various flags which affect the behavior of the signal. You can also refer to this field as sv_onstack.

These symbolic constants can be used to provide values for the sv_flags field of a sigvec structure. This field is a bit mask value, so you bitwise-OR the flags of interest to you together.

int SV_ONSTACK Macro

If this bit is set in the sv_flags field of a sigvec structure, it means to use the signal stack when delivering the signal.

int SV_INTERRUPT

Macro

If this bit is set in the sv_flags field of a sigvec structure, it means that system calls interrupted by this kind of signal should not be restarted if the handler returns; instead, the system calls should return with a EINTR error status. See Section 21.5 [Interrupted Primitives], page 438.

int SV_RESETHAND

Macro

If this bit is set in the sv_flags field of a sigvec structure, it means to reset the action for the signal back to SIG_DFL when the signal is received.

This function is the equivalent of sigaction (see Section 21.3.2 [Advanced Signal Handling], page 419); it installs the action action for the signal signum, returning information about the previous action in effect for that signal in old_action.

int siginterrupt (int signum, int failflag)

Function

This function specifies which approach to use when certain primitives are interrupted by handling signal signum. If failflag is false, signal signum restarts primitives. If failflag is true, handling signum causes these primitives to fail with error code EINTR. See Section 21.5 [Interrupted Primitives], page 438.

21.10.1 BSD Functions for Blocking Signals

int sigmask (int signum)

Macro

This macro returns a signal mask that has the bit for signal signum set. You can bitwise-OR the results of several calls to sigmask together to specify more than one signal. For example,

```
(sigmask (SIGTSTP) | sigmask (SIGSTOP)
    | sigmask (SIGTTIN) | sigmask (SIGTTOU))
```

specifies a mask that includes all the job-control stop signals.

int sigblock (int mask)

Function

This function is the equivalent of sigprocmask (see Section 21.7.3 [Process Signal Mask], page 448) with a how argument of SIG_BLOCK: it adds the signals specified by mask to the calling process's signal mask. The return value is the previous set of blocked signals.

int sigsetmask (int mask)

Function

This function is the equivalent of sigprocmask (see Section 21.7.3 [Process Signal Mask], page 448) with a how argument of SIG_SETMASK: it sets the calling process's signal mask to mask. The return value is the previous set of blocked signals.

int sigpause (int mask)

Function

This function is the equivalent of sigsuspend (see Section 21.8 [Waiting for a Signal], page 454): it sets the calling process's signal mask to mask, and waits for a signal to arrive. On return the previous set of blocked signals is restored.

21.10.2 Using a Separate Signal Stack

A signal stack is a special area of memory to be used as the execution stack during signal handlers. It should be fairly large, to avoid any danger that it will overflow in turn—we recommend at least 16,000 bytes. You can use malloc to allocate the space for the stack. Then call sigstack to tell the system to use that space for the signal stack.

You don't need to write signal handlers differently in order to use a signal stack. Switching from one stack to the other happens automatically. However, some debuggers on some machines may get confused if you examine a stack trace while a handler that uses the signal stack is running.

struct sigstack Data Type

This structure describes a signal stack. It contains the following members:

void *ss_sp

This is the stack pointer.

int ss_onstack

This field is true if the process is currently using this stack.

The sigstack function specifies an alternate stack for use during signal handling. When a signal is received by the process and its action indicates that the signal stack is used, the system arranges a switch to the currently installed signal stack while the handler for that signal is executed.

If oldstack is not a null pointer, information about the currently installed signal stack is returned in the location it points to. If stack is not a null pointer, then this is installed as the new stack for use by signal handlers.

The return value is 0 on success and 1 on failure.

462

22 Process Startup and Termination

Processes are the primitive units for allocation of system resources. Each process has its own address space and (usually) one thread of control. A process executes a program; you can have multiple processes executing the same program, but each process has its own copy of the program within its own address space and executes it independently of the other copies.

This chapter explains what your program should do to handle the startup of a process, to terminate its process, and to receive information (arguments and the environment) from the parent process.

22.1 Program Arguments

The system starts a C program by calling the function main. It is up to you to write a function named main—otherwise, you won't even be able to link your program without errors.

You can define main either to take no arguments, or to take two arguments that represent the command line arguments to the program, like this:

```
int main (int argc, char *argv[])
```

The command line arguments are the whitespace-separated tokens given in the shell command used to invoke the program; thus, in 'cat foo bar', the arguments are 'foo' and 'bar'. The only way a program can look at its command line arguments is via the arguments of main. If main doesn't take arguments, then you cannot get at the command line.

The value of the argc argument is the number of command line arguments. The argv argument is a vector of C strings; its elements are the individual command line argument strings. The file name of the program being run is also included in the vector as the first element; the value of argc counts this element. A null pointer always follows the last element: argv[argc] is this null pointer.

For the command 'cat foo bar', argc is 3 and argv has three elements, "cat", "foo" and "bar".

If the syntax for the command line arguments to your program is simple enough, you can simply pick the arguments off from argv by hand. But unless your program takes a fixed number

of arguments, or all of the arguments are interpreted in the same way (as file names, for example), you are usually better off using getopt to do the parsing.

22.1.1 Program Argument Syntax Conventions

POSIX recommends these conventions for command line arguments. getopt (see Section 22.1.2 [Parsing Options], page 465) makes it easy to implement them.

- Arguments are options if they begin with a hyphen delimiter ('-').
- Multiple options may follow a hyphen delimiter in a single token if the options do not take arguments. Thus, '-abc' is equivalent to '-a -b -c'.
- Option names are single alphanumeric characters (as for isalnum; see Section 4.1 [Classification of Characters], page 61).
- Certain options require an argument. For example, the '-o' command of the 1d command requires an argument—an output file name.
- An option and its argument may or may not appear as separate tokens. (In other words, the whitespace separating them is optional.) Thus, '-o foo' and '-ofoo' are equivalent.
- Options typically precede other non-option arguments.
 - The implementation of getopt in the GNU C library normally makes it appear as if all the option arguments were specified before all the non-option arguments for the purposes of parsing, even if the user of your program intermixed option and non-option arguments. It does this by reordering the elements of the argv array. This behavior is nonstandard; if you want to suppress it, define the _POSIX_OPTION_ORDER environment variable. See Section 22.2.2 [Standard Environment], page 474.
- The argument '--' terminates all options; any following arguments are treated as non-option arguments, even if they begin with a hyphen.
- A token consisting of a single hyphen character is interpreted as an ordinary non-option argument. By convention, it is used to specify input from or output to the standard input and output streams.
- Options may be supplied in any order, or appear multiple times. The interpretation is left up to the particular application program.

GNU adds *long options* to these conventions. Long options consist of '--' followed by a name made of alphanumeric characters and dashes. Option names are typically one to three words long, with hyphens to separate words. Users can abbreviate the option names as long as the abbreviations are unique.

To specify an argument for a long option, write '--name=value'. This syntax enables a long option to accept an argument that is itself optional.

Eventually, the GNU system will provide completion for long option names in the shell.

22.1.2 Parsing Program Options

Here are the details about how to call the **getopt** function. To use this facility, your program must include the header file 'unistd.h'.

int opterr Variable

If the value of this variable is nonzero, then **getopt** prints an error message to the standard error stream if it encounters an unknown option character or an option with a missing required argument. This is the default behavior. If you set this variable to zero, **getopt** does not print any messages, but it still returns the character? to indicate an error.

int optopt Variable

When getopt encounters an unknown option character or an option with a missing required argument, it stores that option character in this variable. You can use this for providing your own diagnostic messages.

int optind Variable

This variable is set by **getopt** to the index of the next element of the *argv* array to be processed. Once **getopt** has found all of the option arguments, you can use this variable to determine where the remaining non-option arguments begin. The initial value of this variable is 1.

char * optarg Variable

This variable is set by **getopt** to point at the value of the option argument, for those options that accept arguments.

int getopt (int argc, char **argv, const char *options) Function

The **getopt** function gets the next option argument from the argument list specified by the *argv* and *argc* arguments. Normally these values come directly from the arguments received by main.

The *options* argument is a string that specifies the option characters that are valid for this program. An option character in this string can be followed by a colon (':') to indicate that it takes a required argument.

If the *options* argument string begins with a hyphen ('-'), this is treated specially. It permits arguments that are not options to be returned as if they were associated with option character '\0'.

The getopt function returns the option character for the next command line option. When no more option arguments are available, it returns -1. There may still be more non-option arguments; you must compare the external variable optind against the argc parameter to check this.

If the option has an argument, **getopt** returns the argument by storing it in the variables optarg. You don't ordinarily need to copy the **optarg** string, since it is a pointer into the original argv array, not into a static area that might be overwritten.

If getopt finds an option character in argv that was not included in options, or a missing option argument, it returns '?' and sets the external variable optopt to the actual option character. If the first character of options is a colon (':'), then getopt returns ':' instead of '?' to indicate a missing option argument. In addition, if the external variable opterr is nonzero (which is the default), getopt prints an error message.

22.1.3 Example of Parsing Arguments with getopt

Here is an example showing how getopt is typically used. The key points to notice are:

- Normally, getopt is called in a loop. When getopt returns -1, indicating no more options are present, the loop terminates.
- A switch statement is used to dispatch on the return value from getopt. In typical use, each case just sets a variable that is used later in the program.
- A second loop is used to process the remaining non-option arguments.

```
#include <unistd.h>
#include <stdio.h>
main (int argc, char **argv)
{
  int aflag = 0;
  int bflag = 0;
  char *cvalue = NULL;
  int index;
  int c;
  opterr = 0;
  while ((c = getopt (argc, argv, "abc:")) != -1)
    switch (c)
      {
      case 'a':
        aflag = 1;
        break;
      case 'b':
        bflag = 1;
        break;
      case 'c':
        cvalue = optarg;
        break;
      case '?':
        if (isprint (optopt))
          fprintf (stderr, "Unknown option '-%c'.\n", optopt);
        else
          fprintf (stderr,
                   "Unknown option character '\\x%x'.\n",
                   optopt);
        return 1;
      default:
        abort ();
      }
```

```
printf ("aflag = %d, bflag = %d, cvalue = %s\n", aflag, bflag, cvalue);
for (index = optind; index < argc; index++)
    printf ("Non-option argument %s\n", argv[index]);
    return 0;
}</pre>
```

Here are some examples showing what this program prints with different combinations of arguments:

```
% testopt
aflag = 0, bflag = 0, cvalue = (null)
% testopt -a -b
aflag = 1, bflag = 1, cvalue = (null)
% testopt -ab
aflag = 1, bflag = 1, cvalue = (null)
% testopt -c foo
aflag = 0, bflag = 0, cvalue = foo
% testopt -cfoo
aflag = 0, bflag = 0, cvalue = foo
% testopt arg1
aflag = 0, bflag = 0, cvalue = (null)
Non-option argument arg1
% testopt -a arg1
aflag = 1, bflag = 0, cvalue = (null)
Non-option argument arg1
% testopt -c foo arg1
aflag = 0, bflag = 0, cvalue = foo
Non-option argument arg1
% testopt -a -- -b
aflag = 1, bflag = 0, cvalue = (null)
Non-option argument -b
% testopt -a -
aflag = 1, bflag = 0, cvalue = (null)
Non-option argument -
```

22.1.4 Parsing Long Options

To accept GNU-style long options as well as single-character options, use getopt_long instead of getopt. You should make every program accept long options if it uses any options, for this takes little extra work and helps beginners remember how to use the program.

struct option Data Type

This structure describes a single long option name for the sake of getopt_long. The argument *longopts* must be an array of these structures, one for each long option. Terminate the array with an element containing all zeros.

The struct option structure has these fields:

const char *name

This field is the name of the option. It is a string.

int has_arg

This field says whether the option takes an argument. It is an integer, and there are three legitimate values: no_argument, required_argument and optional_argument.

int *flag

int val These fields control how to report or act on the option when it occurs.

If flag is a null pointer, then the val is a value which identifies this option. Often these values are chosen to uniquely identify particular long options.

If flag is not a null pointer, it should be the address of an int variable which is the flag for this option. The value in val is the value to store in the flag to indicate that the option was seen.

Decode options from the vector argv (whose length is argc). The argument shortopts describes the short options to accept, just as it does in getopt. The argument longopts describes the long options to accept (see above).

When getopt_long encounters a short option, it does the same thing that getopt would do: it returns the character code for the option, and stores the options argument (if it has one) in optarg.

When getopt_long encounters a long option, it takes actions based on the flag and val fields of the definition of that option.

If flag is a null pointer, then getopt_long returns the contents of val to indicate which option it found. You should arrange distinct values in the val field for options with different meanings, so you can decode these values after getopt_long returns. If the long option is equivalent to a short option, you can use the short option's character code in val.

If flag is not a null pointer, that means this option should just set a flag in the program. The flag is a variable of type int that you define. Put the address of the flag in the flag field. Put in the val field the value you would like this option to store in the flag. In this case, getopt_long returns 0.

For any long option, getopt_long tells you the index in the array longopts of the options definition, by storing it into *indexptr. You can get the name of the option with longopts[*indexptr].name. So you can distinguish among long options either by the values in their val fields or by their indices. You can also distinguish in this way among long options that set flags.

When a long option has an argument, getopt_long puts the argument value in the variable optarg before returning. When the option has no argument, the value in optarg is a null pointer. This is how you can tell whether an optional argument was supplied.

When getopt_long has no more options to handle, it returns -1, and leaves in the variable optind the index in argv of the next remaining argument.

22.1.5 Example of Parsing Long Options

```
#include <stdio.h>
/* Flag set by '--verbose'. */
static int verbose_flag;
int
main (argc, argv)
    int argc;
    char **argv;
```

```
{
  int c;
  while (1)
    {
      static struct option long_options[] =
  /* These options set a flag. */
  {"verbose", 0, &verbose_flag, 1},
  {"brief", 0, &verbose_flag, 0},
  /* These options don't set a flag.
     We distinguish them by their indices. */
  {"add", 1, 0, 0},
  {"append", 0, 0, 0},
  {"delete", 1, 0, 0},
  {"create", 0, 0, 0},
  {"file", 1, 0, 0},
  \{0, 0, 0, 0\}
};
      /* getopt_long stores the option index here. */
      int option_index = 0;
      c = getopt_long (argc, argv, "abc:d:",
       long_options, &option_index);
      /* Detect the end of the options. */
      if (c == -1)
break;
      switch (c)
{
case 0:
  /* If this option set a flag, do nothing else now.
  if (long_options[option_index].flag != 0)
    break;
  printf ("option %s", long_options[option_index].name);
  if (optarg)
    printf (" with arg %s", optarg);
  printf ("\n");
 break;
case 'a':
 puts ("option -a\n");
 break;
case 'b':
  puts ("option -b\n");
 break;
```

```
case 'c':
 printf ("option -c with value '%s'\n", optarg);
 break;
case 'd':
  printf ("option -d with value '%s'\n", optarg);
case '?':
  /* getopt_long already printed an error message. */
 break;
default:
  abort ();
}
  /* Instead of reporting '--verbose'
     and '--brief' as they are encountered,
     we report the final status resulting from them. */
  if (verbose_flag)
    puts ("verbose flag is set");
  /* Print any remaining command line arguments (not options).
  if (optind < argc)</pre>
    {
      printf ("non-option ARGV-elements: ");
      while (optind < argc)
printf ("%s ", argv[optind++]);
      putchar ('\n');
 exit(0);
```

22.2 Environment Variables

When a program is executed, it receives information about the context in which it was invoked in two ways. The first mechanism uses the argv and argc arguments to its main function, and is discussed in Section 22.1 [Program Arguments], page 463. The second mechanism uses environment variables and is discussed in this section.

The argv mechanism is typically used to pass command-line arguments specific to the particular program being invoked. The environment, on the other hand, keeps track of information that is shared by many programs, changes infrequently, and that is less frequently accessed.

The environment variables discussed in this section are the same environment variables that you set using assignments and the export command in the shell. Programs executed from the shell inherit all of the environment variables from the shell.

Standard environment variables are used for information about the user's home directory, terminal type, current locale, and so on; you can define additional variables for other purposes. The set of all environment variables that have values is collectively known as the *environment*.

Names of environment variables are case-sensitive and must not contain the character '='. System-defined environment variables are invariably uppercase.

The values of environment variables can be anything that can be represented as a string. A value must not contain an embedded null character, since this is assumed to terminate the string.

22.2.1 Environment Access

The value of an environment variable can be accessed with the **getenv** function. This is declared in the header file 'stdlib.h'.

char * getenv (const char *name)

Function

This function returns a string that is the value of the environment variable name. You must not modify this string. In some systems not using the GNU library, it might be overwritten by subsequent calls to **getenv** (but not by any other library function). If the environment variable name is not defined, the value is a null pointer.

int putenv (const char *string)

Function

The puterv function adds or removes definitions from the environment. If the *string* is of the form 'name=value', the definition is added to the environment. Otherwise, the *string* is interpreted as the name of an environment variable, and any definition for this variable in the environment is removed.

The GNU library provides this function for compatibility with SVID; it may not be available in other systems.

You can deal directly with the underlying representation of environment objects to add more variables to the environment (for example, to communicate with another program you are about to execute; see Section 23.5 [Executing a File], page 485).

char ** environ Variable

The environment is represented as an array of strings. Each string is of the format 'name=value'. The order in which strings appear in the environment is not significant, but the same name must not appear more than once. The last element of the array is a null pointer.

This variable is declared in the header file 'unistd.h'.

If you just want to get the value of an environment variable, use getenv.

22.2.2 Standard Environment Variables

These environment variables have standard meanings. This doesn't mean that they are always present in the environment; but if these variables are present, they have these meanings, and that you shouldn't try to use these environment variable names for some other purpose.

HOME

This is a string representing the user's *home directory*, or initial default working directory.

The user can set HOME to any value. If you need to make sure to obtain the proper home directory for a particular user, you should not use HOME; instead, look up the user's name in the user database (see Section 25.12 [User Database], page 533).

For most purposes, it is better to use HOME, precisely because this lets the user specify the value.

LOGNAME

This is the name that the user used to log in. Since the value in the environment can be tweaked arbitrarily, this is not a reliable way to identify the user who is running a process; a function like **getlogin** (see Section 25.11 [Who Logged In], page 532) is better for that purpose.

For most purposes, it is better to use LOGNAME, precisely because this lets the user specify the value.

PATH

A path is a sequence of directory names which is used for searching for a file. The variable PATH holds a path used for searching for programs to be run.

The execlp and execvp functions (see Section 23.5 [Executing a File], page 485) use this environment variable, as do many shells and other utilities which are implemented in terms of those functions.

The syntax of a path is a sequence of directory names separated by colons. An empty string instead of a directory name stands for the current directory (see Section 13.1 [Working Directory], page 233).

A typical value for this environment variable might be a string like:

:/bin:/etc:/usr/bin:/usr/new/X11:/usr/new:/usr/local:/usr/local/bin

This means that if the user tries to execute a program named foo, the system will look for files named 'foo', '/bin/foo', '/etc/foo', and so on. The first of these files that exists is the one that is executed.

TERM

This specifies the kind of terminal that is receiving program output. Some programs can make use of this information to take advantage of special escape sequences or terminal modes supported by particular kinds of terminals. Many programs which use the termcap library (see section "Finding a Terminal Description" in *The Termcap Library Manual*) use the TERM environment variable, for example.

TZ

This specifies the time zone. See Section 19.2.5 [TZ Variable], page 383, for information about the format of this string and how it is used.

LANG

This specifies the default locale to use for attribute categories where neither LC_ALL nor the specific environment variable for that category is set. See Chapter 7 [Locales], page 97, for more information about locales.

LC_COLLATE

This specifies what locale to use for string sorting.

LC_CTYPE

This specifies what locale to use for character sets and character classification.

LC_MONETARY

This specifies what locale to use for formatting monetary values.

LC_NUMERIC

This specifies what locale to use for formatting numbers.

LC_TIME

This specifies what locale to use for formatting date/time values.

_POSIX_OPTION_ORDER

If this environment variable is defined, it suppresses the usual reordering of command line arguments by getopt. See Section 22.1.1 [Argument Syntax], page 464.

22.3 Program Termination

The usual way for a program to terminate is simply for its main function to return. The exit status value returned from the main function is used to report information back to the process's parent process or shell.

A program can also terminate normally by calling the exit function.

In addition, programs can be terminated by signals; this is discussed in more detail in Chapter 21 [Signal Handling], page 403. The abort function causes a signal that kills the program.

22.3.1 Normal Termination

A process terminates normally when the program calls exit. Returning from main is equivalent to calling exit, and the value that main returns is used as the argument to exit.

void exit (int status)

Function

The exit function terminates the process with status status. This function does not return.

Normal termination causes the following actions:

- 1. Functions that were registered with the atexit or on_exit functions are called in the reverse order of their registration. This mechanism allows your application to specify its own "cleanup" actions to be performed at program termination. Typically, this is used to do things like saving program state information in a file, or unlocking locks in shared data bases.
- 2. All open streams are closed, writing out any buffered output data. See Section 11.4 [Closing Streams], page 142. In addition, temporary files opened with the tmpfile function are removed; see Section 11.18 [Temporary Files], page 193.
- 3. _exit is called, terminating the program. See Section 22.3.5 [Termination Internals], page 479.

22.3.2 Exit Status

When a program exits, it can return to the parent process a small amount of information about the cause of termination, using the exit status. This is a value between 0 and 255 that the exiting process passes as an argument to exit.

Normally you should use the exit status to report very broad information about success or failure. You can't provide a lot of detail about the reasons for the failure, and most parent processes would not want much detail anyway.

There are conventions for what sorts of status values certain programs should return. The most common convention is simply 0 for success and 1 for failure. Programs that perform comparison use a different convention: they use status 1 to indicate a mismatch, and status 2 to indicate an inability to compare. Your program should follow an existing convention if an existing convention makes sense for it.

A general convention reserves status values 128 and up for special purposes. In particular, the value 128 is used to indicate failure to execute another program in a subprocess. This convention is not universally obeyed, but it is a good idea to follow it in your programs.

Warning: Don't try to use the number of errors as the exit status. This is actually not very useful; a parent process would generally not care how many errors occurred. Worse than that, it does not work, because the status value is truncated to eight bits. Thus, if the program tried to report 256 errors, the parent would receive a report of 0 errors—that is, success.

For the same reason, it does not work to use the value of errno as the exit status—these can exceed 255.

Portability note: Some non-POSIX systems use different conventions for exit status values. For greater portability, you can use the macros EXIT_SUCCESS and EXIT_FAILURE for the conventional status value for success and failure, respectively. They are declared in the file 'stdlib.h'.

int EXIT_SUCCESS

Macro

This macro can be used with the exit function to indicate successful program completion.

On POSIX systems, the value of this macro is 0. On other systems, the value might be some other (possibly non-constant) integer expression.

int EXIT_FAILURE

Macro

This macro can be used with the exit function to indicate unsuccessful program completion in a general sense.

On POSIX systems, the value of this macro is 1. On other systems, the value might be some other (possibly non-constant) integer expression. Other nonzero status values also indicate future. Certain programs use different nonzero status values to indicate particular kinds of "non-success". For example, diff uses status value 1 to mean that the files are different, and 2 or more to mean that there was difficulty in opening the files.

22.3.3 Cleanups on Exit

Your program can arrange to run its own cleanup functions if normal termination happens. If you are writing a library for use in various application programs, then it is unreliable to insist that all applications call the library's cleanup functions explicitly before exiting. It is much more robust to make the cleanup invisible to the application, by setting up a cleanup function in the library itself using atexit or on_exit.

```
int atexit (void (*function) (void))
```

Function

The atexit function registers the function function to be called at normal program termination. The function is called with no arguments.

The return value from atexit is zero on success and nonzero if the function cannot be registered.

```
int on_exit (void (*function)(int status, void *arg), void *arg)
```

Function

This function is a somewhat more powerful variant of atexit. It accepts two arguments, a function function and an arbitrary pointer arg. At normal program termination, the function is called with two arguments: the status value passed to exit, and the arg.

This function is included in the GNU C library only for compatibility for SunOS, and may not be supported by other implementations.

Here's a trivial program that illustrates the use of exit and atexit:

```
#include <stdio.h>
#include <stdlib.h>

void
bye (void)
```

```
{
   puts ("Goodbye, cruel world....");
}
int
main (void)
{
   atexit (bye);
   exit (EXIT_SUCCESS);
}
```

When this program is executed, it just prints the message and exits.

22.3.4 Aborting a Program

You can abort your program using the abort function. The prototype for this function is in 'stdlib.h'.

void abort (void) Function

The abort function causes abnormal program termination. This does not execute cleanup functions registered with atexit or on_exit.

This function actually terminates the process by raising a SIGABRT signal, and your program can include a handler to intercept this signal; see Chapter 21 [Signal Handling], page 403.

Future Change Warning: Proposed Federal censorship regulations may prohibit us from giving you information about the possibility of calling this function. We would be required to say that this is not an acceptable way of terminating a program.

22.3.5 Termination Internals

The _exit function is the primitive used for process termination by exit. It is declared in the header file 'unistd.h'.

The GNU C Library

void _exit (int status)

Function

The _exit function is the primitive for causing a process to terminate with status status. Calling this function does not execute cleanup functions registered with atexit or on_exit.

When a process terminates for any reason—either by an explicit termination call, or termination as a result of a signal—the following things happen:

- All open file descriptors in the process are closed. See Chapter 12 [Low-Level I/O], page 203.
- The low-order 8 bits of the return status code are saved to be reported back to the parent process via wait or waitpid; see Section 23.6 [Process Completion], page 488.
- Any child processes of the process being terminated are assigned a new parent process. (This is the init process, with process ID 1.)
- A SIGCHLD signal is sent to the parent process.
- If the process is a session leader that has a controlling terminal, then a SIGHUP signal is sent to each process in the foreground job, and the controlling terminal is disassociated from that session. See Chapter 24 [Job Control], page 495.
- If termination of a process causes a process group to become orphaned, and any member of that process group is stopped, then a SIGHUP signal and a SIGCONT signal are sent to each process in the group. See Chapter 24 [Job Control], page 495.

23 Child Processes

Processes are the primitive units for allocation of system resources. Each process has its own address space and (usually) one thread of control. A process executes a program; you can have multiple processes executing the same program, but each process has its own copy of the program within its own address space and executes it independently of the other copies.

Processes are organized hierarchically. Each process has a parent process which explicitly arranged to create it. The processes created by a given parent are called its *child processes*. A child inherits many of its attributes from the parent process.

This chapter describes how a program can create, terminate, and control child processes. Actually, there are three distinct operations involved: creating a new child process, causing the new process to execute a program, and coordinating the completion of the child process with the original program.

The system function provides a simple, portable mechanism for running another program; it does all three steps automatically. If you need more control over the details of how this is done, you can use the primitive functions to do each step individually instead.

23.1 Running a Command

The easy way to run another program is to use the **system** function. This function does all the work of running a subprogram, but it doesn't give you much control over the details: you have to wait until the subprogram terminates before you can do anything else.

int system (const char *command)

Function

This function executes *command* as a shell command. In the GNU C library, it always uses the default shell sh to run the command. In particular, it searches the directories in PATH to find programs to execute. The return value is -1 if it wasn't possible to create the shell process, and otherwise is the status of the shell process. See Section 23.6 [Process Completion], page 488, for details on how this status code can be interpreted.

The system function is declared in the header file 'stdlib.h'.

Portability Note: Some C implementations may not have any notion of a command processor that can execute other programs. You can determine whether a command processor exists by executing system (NULL); if the return value is nonzero, a command processor is available.

The popen and pclose functions (see Section 14.2 [Pipe to a Subprocess], page 265) are closely related to the system function. They allow the parent process to communicate with the standard input and output channels of the command being executed.

23.2 Process Creation Concepts

This section gives an overview of processes and of the steps involved in creating a process and making it run another program.

Each process is named by a *process ID* number. A unique process ID is allocated to each process when it is created. The *lifetime* of a process ends when its termination is reported to its parent process; at that time, all of the process resources, including its process ID, are freed.

Processes are created with the fork system call (so the operation of creating a new process is sometimes called *forking* a process). The *child process* created by fork is an exact clone of the original *parent process*, except that it has its own process ID.

After forking a child process, both the parent and child processes continue to execute normally. If you want your program to wait for a child process to finish executing before continuing, you must do this explicitly after the fork operation, by calling wait or waitpid (see Section 23.6 [Process Completion], page 488). These functions give you limited information about why the child terminated—for example, its exit status code.

A newly forked child process continues to execute the same program as its parent process, at the point where the fork call returns. You can use the return value from fork to tell whether the program is running in the parent process or the child.

Having several processes run the same program is only occasionally useful. But the child can execute another program using one of the exec functions; see Section 23.5 [Executing a File], page 485. The program that the process is executing is called its process image. Starting execution of a new program causes the process to forget all about its previous process image; when the new program exits, the process exits too, instead of returning to the previous process image.

23.3 Process Identification

The pid_t data type represents process IDs. You can get the process ID of a process by calling getpid. The function getppid returns the process ID of the parent of the current process (this is also known as the parent process ID). Your program should include the header files 'unistd.h' and 'sys/types.h' to use these functions.

pid_t Data Type

The pid_t data type is a signed integer type which is capable of representing a process ID. In the GNU library, this is an int.

pid_t getpid (void)

Function

The getpid function returns the process ID of the current process.

pid_t getppid (void)

Function

The getppid function returns the process ID of the parent of the current process.

23.4 Creating a Process

The fork function is the primitive for creating a process. It is declared in the header file 'unistd.h'.

pid_t fork (void) Function

The fork function creates a new process.

If the operation is successful, there are then both parent and child processes and both see fork return, but with different values: it returns a value of 0 in the child process and returns the child's process ID in the parent process.

If process creation failed, fork returns a value of -1 in the parent process. The following errno error conditions are defined for fork:

EAGAIN There aren't enough system resources to create another process, or the user already has too many processes running.

ENOMEM The process requires more space than the system can supply.

The specific attributes of the child process that differ from the parent process are:

- The child process has its own unique process ID.
- The parent process ID of the child process is the process ID of its parent process.
- The child process gets its own copies of the parent process's open file descriptors. Subsequently changing attributes of the file descriptors in the parent process won't affect the file descriptors in the child, and vice versa. See Section 12.7 [Control Operations], page 219.
- The elapsed processor times for the child process are set to zero; see Section 19.1 [Processor Time], page 371.
- The child doesn't inherit file locks set by the parent process. See Section 12.7 [Control Operations], page 219.
- The child doesn't inherit alarms set by the parent process. See Section 19.3 [Setting an Alarm], page 387.
- The set of pending signals (see Section 21.1.3 [Delivery of Signal], page 405) for the child process is cleared. (The child process inherits its mask of blocked signals and signal actions from the parent process.)

pid_t **vfork** (void)

Function

The vfork function is similar to fork but more efficient; however, there are restrictions you must follow to use it safely.

While fork makes a complete copy of the calling process's address space and allows both the parent and child to execute independently, vfork does not make this copy. Instead, the child process created with vfork shares its parent's address space until it calls one of the exec functions. In the meantime, the parent process suspends execution.

You must be very careful not to allow the child process created with vfork to modify any global data or even local variables shared with the parent. Furthermore, the child process cannot return from (or do a long jump out of) the function that called vfork! This would leave the parent process's control information very confused. If in doubt, use fork instead.

Some operating systems don't really implement vfork. The GNU C library permits you to use vfork on all systems, but actually executes fork if vfork isn't available. If you follow the proper precautions for using vfork, your program will still work even if the system uses fork instead.

23.5 Executing a File

This section describes the exec family of functions, for executing a file as a process image. You can use these functions to make a child process execute a new program after it has been forked.

The functions in this family differ in how you specify the arguments, but otherwise they all do the same thing. They are declared in the header file 'unistd.h'.

int execv (const char *filename, char *const argv[])

Function

The execv function executes the file named by filename as a new process image.

The argv argument is an array of null-terminated strings that is used to provide a value for the argv argument to the main function of the program to be executed. The last element of this array must be a null pointer. See Section 22.1 [Program Arguments], page 463, for information on how programs can access these arguments.

The environment for the new process image is taken from the environ variable of the current process image; see Section 22.2 [Environment Variables], page 472, for information about environments.

int execl (const char *filename, const char *arg0, ...)

Function

This is similar to execv, but the argv strings are specified individually instead of as an array. A null pointer must be passed as the last such argument.

int execve (const char *filename, char *const argv[], char *const env[])

Function

This is similar to execv, but permits you to specify the environment for the new program explicitly as the *env* argument. This should be an array of strings in the same format as for the environ variable; see Section 22.2.1 [Environment Access], page 473.

int execle (const char *filename, const char *arg0, char *const $env[], \ldots$)

Function

This is similar to exec1, but permits you to specify the environment for the new program explicitly. The environment argument is passed following the null pointer that marks the last argv argument, and should be an array of strings in the same format as for the environ variable.

int execvp (const char *filename, char *const argv[])

Function

The execvp function is similar to execv, except that it searches the directories listed in the PATH environment variable (see Section 22.2.2 [Standard Environment], page 474) to find the full file name of a file from *filename* if *filename* does not contain a slash.

This function is useful for executing system utility programs, because it looks for them in the places that the user has chosen. Shells use it to run the commands that users type.

int execlp (const char *filename, const char *arg0, ...)

Function

This function is like exec1, except that it performs the same file name searching as the execvp function.

The size of the argument list and environment list taken together must not be greater than ARG_MAX bytes. See Section 27.1 [General Limits], page 545. In the GNU system, the size (which compares against ARG_MAX) includes, for each string, the number of characters in the string, plus the size of a char *, plus one, rounded up to a multiple of the size of a char *. Other systems may have somewhat different rules for counting.

These functions normally don't return, since execution of a new program causes the currently executing program to go away completely. A value of -1 is returned in the event of a failure. In addition to the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following errno error conditions are defined for these functions:

E2BIG

The combined size of the new program's argument list and environment list is larger than ARG_MAX bytes. The GNU system has no specific limit on the argument list size, so this error code cannot result, but you may get ENOMEM instead if the arguments are too big for available memory.

ENOEXEC The specified file can't be executed because it isn't in the right format.

Executing the specified file requires more storage than is available.

If execution of the new file succeeds, it updates the access time field of the file as if the file had been read. See Section 13.8.9 [File Times], page 259, for more details about access times of files.

The point at which the file is closed again is not specified, but is at some point before the process exits or before another process image is executed.

Executing a new process image completely changes the contents of memory, copying only the argument and environment strings to new locations. But many other attributes of the process are unchanged:

- The process ID and the parent process ID. See Section 23.2 [Process Creation Concepts], page 482.
- Session and process group membership. See Section 24.1 [Concepts of Job Control], page 495.
- Real user ID and group ID, and supplementary group IDs. See Section 25.2 [Process Persona], page 521.
- Pending alarms. See Section 19.3 [Setting an Alarm], page 387.
- Current working directory and root directory. See Section 13.1 [Working Directory], page 233.
- File mode creation mask. See Section 13.8.7 [Setting Permissions], page 255.
- Process signal mask; see Section 21.7.3 [Process Signal Mask], page 448.
- Pending signals; see Section 21.7 [Blocking Signals], page 445.
- Elapsed processor time associated with the process; see Section 19.1 [Processor Time], page 371.

If the set-user-ID and set-group-ID mode bits of the process image file are set, this affects the effective user ID and effective group ID (respectively) of the process. These concepts are discussed in detail in Section 25.2 [Process Persona], page 521.

Signals that are set to be ignored in the existing process image are also set to be ignored in the new process image. All other signals are set to the default action in the new process image. For more information about signals, see Chapter 21 [Signal Handling], page 403.

File descriptors open in the existing process image remain open in the new process image, unless they have the FD_CLOEXEC (close-on-exec) flag set. The files that remain open inherit all attributes of the open file description from the existing process image, including file locks. File descriptors are discussed in Chapter 12 [Low-Level I/O], page 203.

Streams, by contrast, cannot survive through exec functions, because they are located in the memory of the process itself. The new process image has no streams except those it creates afresh. Each of the streams in the pre-exec process image has a descriptor inside it, and these descriptors do survive through exec (provided that they do not have FD_CLOEXEC set. The new process image can reconnect these to new streams using fdopen (see Section 12.4 [Descriptors and Streams], page 212).

23.6 Process Completion

The functions described in this section are used to wait for a child process to terminate or stop, and determine its status. These functions are declared in the header file 'sys/wait.h'.

pid_t waitpid (pid_t pid, int *status ptr, int options)

Function

The waitpid function is used to request status information from a child process whose process ID is *pid*. Normally, the calling process is suspended until the child process makes status information available by terminating.

Other values for the pid argument have special interpretations. A value of -1 or WAIT_ANY requests status information for any child process; a value of 0 or WAIT_MYPGRP requests information for any child process in the same process group as the calling process; and any other negative value -pgid requests information for any child process whose process group ID is pgid.

If status information for a child process is available immediately, this function returns immediately without waiting. If more than one eligible child process has status information available, one of them is chosen randomly, and its status is returned immediately. To get the status from the other eligible child processes, you need to call waitpid again.

The options argument is a bit mask. Its value should be the bitwise OR (that is, the '|' operator) of zero or more of the WNOHANG and WUNTRACED flags. You can use the WNOHANG flag to indicate that the parent process shouldn't wait; and the WUNTRACED flag to request status information from stopped processes as well as processes that have terminated.

The status information from the child process is stored in the object that $status_ptr$ points to, unless $status_ptr$ is a null pointer.

The return value is normally the process ID of the child process whose status is reported. If the WNOHANG option was specified and no child process is waiting to be noticed, the value is zero. A value of -1 is returned in case of error. The following errno error conditions are defined for this function:

EINTR The function was interrupted by delivery of a signal to the calling process. See Section 21.5 [Interrupted Primitives], page 438.

ECHILD There are no child processes to wait for, or the specified *pid* is not a child of the calling process.

EINVAL An invalid value was provided for the options argument.

These symbolic constants are defined as values for the pid argument to the waitpid function.

WAIT_ANY

This constant macro (whose value is -1) specifies that waitpid should return status information about any child process.

WAIT_MYPGRP

This constant (with value 0) specifies that waitpid should return status information about any child process in the same process group as the calling process.

These symbolic constants are defined as flags for the *options* argument to the waitpid function. You can bitwise-OR the flags together to obtain a value to use as the argument.

WNOHANG

This flag specifies that waitpid should return immediately instead of waiting, if there is no child process ready to be noticed.

WUNTRACED

This flag specifies that waitpid should report the status of any child processes that have been stopped as well as those that have terminated.

pid_t wait (int *status ptr)

Function

This is a simplified version of waitpid, and is used to wait until any one child process terminates. The call:

```
wait (&status)
```

is exactly equivalent to:

```
waitpid (-1, &status, 0)
```

Here's an example of how to use waitpid to get the status from all child processes that have terminated, without ever waiting. This function is designed to be a handler for SIGCHLD, the signal that indicates that at least one child process has terminated.

```
void
sigchld_handler (int signum)
  int pid;
  int status;
  while (1)
    {
      pid = waitpid (WAIT_ANY, &status, WNOHANG);
      if (pid < 0)
        {
          perror ("waitpid");
          break;
        }
      if (pid == 0)
        break;
      notice_termination (pid, status);
}
```

23.7 Process Completion Status

If the exit status value (see Section 22.3 [Program Termination], page 476) of the child process is zero, then the status value reported by waitpid or wait is also zero. You can test for other kinds of information encoded in the returned status value using the following macros. These macros are defined in the header file 'sys/wait.h'.

int WIFEXITED (int status)

Macro

This macro returns a nonzero value if the child process terminated normally with exit or _exit.

int WEXITSTATUS (int status)

Macro

If WIFEXITED is true of status, this macro returns the low-order 8 bits of the exit status value from the child process. See Section 22.3.2 [Exit Status], page 476.

int WIFSIGNALED (int status)

Macro

This macro returns a nonzero value if the child process terminated because it received a signal that was not handled. See Chapter 21 [Signal Handling], page 403.

int WTERMSIG (int status)

Macro

If WIFSIGNALED is true of status, this macro returns the signal number of the signal that terminated the child process.

int WCOREDUMP (int status)

Macro

This macro returns a nonzero value if the child process terminated and produced a core dump.

int WIFSTOPPED (int status)

Macro

This macro returns a nonzero value if the child process is stopped.

int WSTOPSIG (int status)

Macro

If WIFSTOPPED is true of *status*, this macro returns the signal number of the signal that caused the child process to stop.

23.8 BSD Process Wait Functions

The GNU library also provides these related facilities for compatibility with BSD Unix. BSD uses the union wait data type to represent status values rather than an int. The two representations are actually interchangeable; they describe the same bit patterns. The GNU C Library defines macros such as WEXITSTATUS so that they will work on either kind of object, and the wait function is defined to accept either type of pointer as its status-ptr argument.

These functions are declared in 'sys/wait.h'.

union wait Data Type

This data type represents program termination status values. It has the following members:

```
int w_termsig
```

This member is equivalent to the WTERMSIG macro.

int w_coredump

This member is equivalent to the WCOREDUMP macro.

int w_retcode

This member is equivalent to the WEXISTATUS macro.

int w_stopsig

This member is equivalent to the WSTOPSIG macro.

Instead of accessing these members directly, you should use the equivalent macros.

If usage is a null pointer, wait3 is equivalent to waitpid (-1, status ptr, options).

If usage is not null, wait3 stores usage figures for the child process in *rusage (but only if the child has terminated, not if it has stopped). See Section 19.5 [Resource Usage], page 391.

If usage is a null pointer, wait4 is equivalent to waitpid (pid, status ptr, options).

If usage is not null, wait4 stores usage figures for the child process in *rusage (but only if the child has terminated, not if it has stopped). See Section 19.5 [Resource Usage], page 391.

23.9 Process Creation Example

Here is an example program showing how you might write a function similar to the built-in system. It executes its *command* argument using the equivalent of 'sh -c *command*'.

```
#include <stddef.h>
#include <stdlib.h>
#include <unistd.h>
```

```
#include <sys/types.h>
#include <sys/wait.h>
/* Execute the command using this shell program. */
#define SHELL "/bin/sh"
int
my_system (const char *command)
{
  int status;
 pid_t pid;
 pid = fork ();
  if (pid == 0)
    {
      /* This is the child process. Execute the shell command. */
      execl (SHELL, SHELL, "-c", command, NULL);
      _exit (EXIT_FAILURE);
  else if (pid < 0)
    /* The fork failed. Report failure. */
    status = -1;
    /* This is the parent process. Wait for the child to complete. */
    if (waitpid (pid, &status, 0) != pid)
      status = -1;
  return status;
```

There are a couple of things you should pay attention to in this example.

Remember that the first argv argument supplied to the program represents the name of the program being executed. That is why, in the call to execl, SHELL is supplied once to name the program to execute and a second time to supply a value for argv[0].

The execl call in the child process doesn't return if it is successful. If it fails, you must do something to make the child process terminate. Just returning a bad status code with return would leave two processes running the original program. Instead, the right behavior is for the child process to report failure to its parent process.

Call _exit to accomplish this. The reason for using _exit instead of exit is to avoid flushing fully buffered streams such as stdout. The buffers of these streams probably contain data that was copied from the parent process by the fork, data that will be output eventually by the parent

process. Calling exit in the child would output the data twice. See Section 22.3.5 [Termination Internals], page 479.

24 Job Control

Job control refers to the protocol for allowing a user to move between multiple process groups (or jobs) within a single login session. The job control facilities are set up so that appropriate behavior for most programs happens automatically and they need not do anything special about job control. So you can probably ignore the material in this chapter unless you are writing a shell or login program.

You need to be familiar with concepts relating to process creation (see Section 23.2 [Process Creation Concepts], page 482) and signal handling (see Chapter 21 [Signal Handling], page 403) in order to understand this material presented in this chapter.

24.1 Concepts of Job Control

The fundamental purpose of an interactive shell is to read commands from the user's terminal and create processes to execute the programs specified by those commands. It can do this using the fork (see Section 23.4 [Creating a Process], page 483) and exec (see Section 23.5 [Executing a File], page 485) functions.

A single command may run just one process—but often one command uses several processes. If you use the '|' operator in a shell command, you explicitly request several programs in their own processes. But even if you run just one program, it can use multiple processes internally. For example, a single compilation command such as 'cc -c foo.c' typically uses four processes (though normally only two at any given time). If you run make, its job is to run other programs in separate processes.

The processes belonging to a single command are called a *process group* or *job*. This is so that you can operate on all of them at once. For example, typing C-c sends the signal SIGINT to terminate all the processes in the foreground process group.

A session is a larger group of processes. Normally all the processes that stem from a single login belong to the same session.

Every process belongs to a process group. When a process is created, it becomes a member of the same process group and session as its parent process. You can put it in another process group using the **setpgid** function, provided the process group belongs to the same session.

The only way to put a process in a different session is to make it the initial process of a new session, or a session leader, using the setsid function. This also puts the session leader into a new process group, and you can't move it out of that process group again.

Usually, new sessions are created by the system login program, and the session leader is the process running the user's login shell.

A shell that supports job control must arrange to control which job can use the terminal at any time. Otherwise there might be multiple jobs trying to read from the terminal at once, and confusion about which process should receive the input typed by the user. To prevent this, the shell must cooperate with the terminal driver using the protocol described in this chapter.

The shell can give unlimited access to the controlling terminal to only one process group at a time. This is called the *foreground job* on that controlling terminal. Other process groups managed by the shell that are executing without such access to the terminal are called *background jobs*.

If a background job needs to read from or write to its controlling terminal, it is *stopped* by the terminal driver. The user can stop a foreground job by typing the SUSP character (see Section 16.4.9 [Special Characters], page 335) and a program can stop any job by sending it a SIGSTOP signal. It's the responsibility of the shell to notice when jobs stop, to notify the user about them, and to provide mechanisms for allowing the user to interactively continue stopped jobs and switch jobs between foreground and background.

See Section 24.4 [Access to the Terminal], page 497, for more information about I/O to the controlling terminal,

24.2 Job Control is Optional

496

Not all operating systems support job control. The GNU system does support job control, but if you are using the GNU library on some other system, that system may not support job control itself.

You can use the _POSIX_JOB_CONTROL macro to test at compile-time whether the system supports job control. See Section 27.2 [System Options], page 547.

If job control is not supported, then there can be only one process group per session, which behaves as if it were always in the foreground. The functions for creating additional process groups simply fail with the error code ENOSYS.

The macros naming the various job control signals (see Section 21.2.5 [Job Control Signals], page 412) are defined even if job control is not supported. However, the system never generates these signals, and attempts to send a job control signal or examine or specify their actions report errors or do nothing.

24.3 Controlling Terminal of a Process

One of the attributes of a process is its controlling terminal. Child processes created with fork inherit the controlling terminal from their parent process. In this way, all the processes in a session inherit the controlling terminal from the session leader. A session leader that has control of a terminal is called the *controlling process* of that terminal.

You generally do not need to worry about the exact mechanism used to allocate a controlling terminal to a session, since it is done for you by the system when you log in.

An individual process disconnects from its controlling terminal when it calls **setsid** to become the leader of a new session. See Section 24.7.2 [Process Group Functions], page 516.

24.4 Access to the Controlling Terminal

Processes in the foreground job of a controlling terminal have unrestricted access to that terminal; background processes do not. This section describes in more detail what happens when a process in a background job tries to access its controlling terminal.

When a process in a background job tries to read from its controlling terminal, the process group is usually sent a SIGTTIN signal. This normally causes all of the processes in that group to stop (unless they handle the signal and don't stop themselves). However, if the reading process is ignoring or blocking this signal, then read fails with an EIO error instead.

Similarly, when a process in a background job tries to write to its controlling terminal, the default behavior is to send a SIGTTOU signal to the process group. However, the behavior is modified by the TOSTOP bit of the local modes flags (see Section 16.4.7 [Local Modes], page 331). If this bit is not set (which is the default), then writing to the controlling terminal is always permitted without sending a signal. Writing is also permitted if the SIGTTOU signal is being ignored or blocked by the writing process.

The GNU C Library

Most other terminal operations that a program can do are treated as reading or as writing. (The description of each operation should say which.)

For more information about the primitive read and write functions, see Section 12.2 [I/O Primitives], page 206.

24.5 Orphaned Process Groups

498

When a controlling process terminates, its terminal becomes free and a new session can be established on it. (In fact, another user could log in on the terminal.) This could cause a problem if any processes from the old session are still trying to use that terminal.

To prevent problems, process groups that continue running even after the session leader has terminated are marked as *orphaned process groups*. Processes in an orphaned process group cannot read from or write to the controlling terminal. Attempts to do so will fail with an EIO error.

When a process group becomes an orphan, its processes are sent a SIGHUP signal. Ordinarily, this causes the processes to terminate. However, if a program ignores this signal or establishes a handler for it (see Chapter 21 [Signal Handling], page 403), it can continue running as in the orphan process group even after its controlling process terminates; but it still cannot access the terminal any more.

24.6 Implementing a Job Control Shell

This section describes what a shell must do to implement job control, by presenting an extensive sample program to illustrate the concepts involved.

- Section 24.6.1 [Data Structures], page 499, introduces the example and presents its primary data structures.
- Section 24.6.2 [Initializing the Shell], page 501, discusses actions which the shell must perform to prepare for job control.
- Section 24.6.3 [Launching Jobs], page 503, includes information about how to create jobs to execute commands.
- Section 24.6.4 [Foreground and Background], page 507, discusses what the shell should do differently when launching a job in the foreground as opposed to a background job.

- Section 24.6.5 [Stopped and Terminated Jobs], page 509, discusses reporting of job status back to the shell.
- Section 24.6.6 [Continuing Stopped Jobs], page 514, tells you how to continue jobs that have been stopped.
- Section 24.6.7 [Missing Pieces], page 515, discusses other parts of the shell.

24.6.1 Data Structures for the Shell

All of the program examples included in this chapter are part of a simple shell program. This section presents data structures and utility functions which are used throughout the example.

The sample shell deals mainly with two data structures. The job type contains information about a job, which is a set of subprocesses linked together with pipes. The process type holds information about a single subprocess. Here are the relevant data structure declarations:

```
/* A process is a single process. */
typedef struct process
{
  struct process *next;
                                 /* next process in pipeline */
  char **argv;
                                 /* for exec */
  pid_t pid;
                                 /* process ID */
  char completed;
                                 /* true if process has completed */
  char stopped;
                                 /* true if process has stopped */
  int status;
                                 /* reported status value */
} process;
```

```
/* A job is a pipeline of processes. */
typedef struct job
{
                                /* next active job */
  struct job *next;
                                /* command line, used for messages */
  char *command;
                                /* list of processes in this job */
  process *first_process;
                                 /* process group ID */
  pid_t pgid;
                                /* true if user told about stopped job */
  char notified;
                                /* saved terminal modes */
  struct termios tmodes;
  int stdin, stdout, stderr; /* standard i/o channels */
} job;
/* The active jobs are linked into a list. This is its head.
job *first_job = NULL;
```

Here are some utility functions that are used for operating on job objects.

```
/* Find the active job with the indicated pgid. */
job *
find_job (pid_t pgid)
{
   job *j;
   for (j = first_job; j; j = j->next)
      if (j->pgid == pgid)
      return j;
   return NULL;
}
```

```
/* Return true if all processes in the job have stopped or completed. */
job_is_stopped (job *j)
{
 process *p;
  for (p = j->first_process; p; p = p->next)
    if (!p->completed && !p->stopped)
      return 0;
  return 1;
}
/* Return true if all processes in the job have completed. */
job_is_completed (job *j)
 process *p;
 for (p = j->first_process; p; p = p->next)
    if (!p->completed)
      return 0;
  return 1;
}
```

24.6.2 Initializing the Shell

When a shell program that normally performs job control is started, it has to be careful in case it has been invoked from another shell that is already doing its own job control.

A subshell that runs interactively has to ensure that it has been placed in the foreground by its parent shell before it can enable job control itself. It does this by getting its initial process group ID with the getpgrp function, and comparing it to the process group ID of the current foreground job associated with its controlling terminal (which can be retrieved using the tcgetpgrp function).

If the subshell is not running as a foreground job, it must stop itself by sending a SIGTTIN signal to its own process group. It may not arbitrarily put itself into the foreground; it must wait for the user to tell the parent shell to do this. If the subshell is continued again, it should repeat the check and stop itself again if it is still not in the foreground.

Once the subshell has been placed into the foreground by its parent shell, it can enable its own job control. It does this by calling setpgid to put itself into its own process group, and then calling tcsetpgrp to place this process group into the foreground.

When a shell enables job control, it should set itself to ignore all the job control stop signals so that it doesn't accidentally stop itself. You can do this by setting the action for all the stop signals to SIG_IGN.

A subshell that runs non-interactively cannot and should not support job control. It must leave all processes it creates in the same process group as the shell itself; this allows the non-interactive shell and its child processes to be treated as a single job by the parent shell. This is easy to do—just don't use any of the job control primitives—but you must remember to make the shell do it.

Here is the initialization code for the sample shell that shows how to do all of this.

```
/* Keep track of attributes of the shell. */
#include <sys/types.h>
#include <termios.h>
#include <unistd.h>
pid_t shell_pgid;
struct termios shell_tmodes;
int shell_terminal;
int shell_is_interactive;
/* Make sure the shell is running interactively as the foreground job
   before proceeding. */
void
init_shell ()
  /* See if we are running interactively. */
  shell_terminal = STDIN_FILENO;
  shell_is_interactive = isatty (shell_terminal);
  if (shell_is_interactive)
      /* Loop until we are in the foreground. */
      while (tcgetpgrp (shell_terminal) != (shell_pgid = getpgrp ()))
        kill (- shell_pgid, SIGTTIN);
```

```
/* Ignore interactive and job-control signals. */
      signal (SIGINT, SIG_IGN);
      signal (SIGQUIT, SIG_IGN);
      signal (SIGTSTP, SIG_IGN);
      signal (SIGTTIN, SIG_IGN);
      signal (SIGTTOU, SIG_IGN);
      signal (SIGCHLD, SIG_IGN);
      /* Put ourselves in our own process group. */
      shell_pgid = getpid ();
      if (setpgid (shell_pgid, shell_pgid) < 0)</pre>
          perror ("Couldn't put the shell in its own process group");
          exit (1);
        }
      /* Grab control of the terminal. */
      tcsetpgrp (shell_terminal, shell_pgid);
      /* Save default terminal attributes for shell. */
      tcgetattr (shell_terminal, &shell_tmodes);
    }
}
```

24.6.3 Launching Jobs

Once the shell has taken responsibility for performing job control on its controlling terminal, it can launch jobs in response to commands typed by the user.

To create the processes in a process group, you use the same fork and exec functions described in Section 23.2 [Process Creation Concepts], page 482. Since there are multiple child processes involved, though, things are a little more complicated and you must be careful to do things in the right order. Otherwise, nasty race conditions can result.

You have two choices for how to structure the tree of parent-child relationships among the processes. You can either make all the processes in the process group be children of the shell process, or you can make one process in group be the ancestor of all the other processes in that group. The sample shell program presented in this chapter uses the first approach because it makes bookkeeping somewhat simpler.

As each process is forked, it should put itself in the new process group by calling setpgid; see Section 24.7.2 [Process Group Functions], page 516. The first process in the new group becomes its process group leader, and its process ID becomes the process group ID for the group.

The shell should also call setpgid to put each of its child processes into the new process group. This is because there is a potential timing problem: each child process must be put in the process group before it begins executing a new program, and the shell depends on having all the child processes in the group before it continues executing. If both the child processes and the shell call setpgid, this ensures that the right things happen no matter which process gets to it first.

If the job is being launched as a foreground job, the new process group also needs to be put into the foreground on the controlling terminal using tcsetpgrp. Again, this should be done by the shell as well as by each of its child processes, to avoid race conditions.

The next thing each child process should do is to reset its signal actions.

During initialization, the shell process set itself to ignore job control signals; see Section 24.6.2 [Initializing the Shell], page 501. As a result, any child processes it creates also ignore these signals by inheritance. This is definitely undesirable, so each child process should explicitly set the actions for these signals back to SIG_DFL just after it is forked.

Since shells follow this convention, applications can assume that they inherit the correct handling of these signals from the parent process. But every application has a responsibility not to mess up the handling of stop signals. Applications that disable the normal interpretation of the SUSP character should provide some other mechanism for the user to stop the job. When the user invokes this mechanism, the program should send a SIGTSTP signal to the process group of the process, not just to the process itself. See Section 21.6.2 [Signaling Another Process], page 441.

Finally, each child process should call exec in the normal way. This is also the point at which redirection of the standard input and output channels should be handled. See Section 12.8 [Duplicating Descriptors], page 220, for an explanation of how to do this.

Here is the function from the sample shell program that is responsible for launching a program. The function is executed by each child process immediately after it has been forked by the shell, and never returns.

void

504

```
launch_process (process *p, pid_t pgid,
                 int infile, int outfile, int errfile,
                 int foreground)
{
 pid_t pid;
  if (shell_is_interactive)
      /* Put the process into the process group and give the process group
         the terminal, if appropriate.
         This has to be done both by the shell and in the individual
         child processes because of potential race conditions. */
      pid = getpid ();
      if (pgid == 0) pgid = pid;
      setpgid (pid, pgid);
      if (foreground)
        tcsetpgrp (shell_terminal, pgid);
      /* Set the handling for job control signals back to the default. */
      signal (SIGINT, SIG_DFL);
      signal (SIGQUIT, SIG_DFL);
      signal (SIGTSTP, SIG_DFL);
      signal (SIGTTIN, SIG_DFL);
      signal (SIGTTOU, SIG_DFL);
      signal (SIGCHLD, SIG_DFL);
    }
  /* Set the standard input/output channels of the new process. */
  if (infile != STDIN_FILENO)
    {
      dup2 (infile, STDIN_FILENO);
      close (infile);
    }
  if (outfile != STDOUT_FILENO)
      dup2 (outfile, STDOUT_FILENO);
      close (outfile);
    }
  if (errfile != STDERR_FILENO)
      dup2 (errfile, STDERR_FILENO);
      close (errfile);
  /* Exec the new process. Make sure we exit. */
  execvp (p->argv[0], p->argv);
 perror ("execvp");
  exit (1);
}
```

If the shell is not running interactively, this function does not do anything with process groups or signals. Remember that a shell not performing job control must keep all of its subprocesses in the same process group as the shell itself.

Next, here is the function that actually launches a complete job. After creating the child processes, this function calls some other functions to put the newly created job into the foreground or background; these are discussed in Section 24.6.4 [Foreground and Background], page 507.

```
void
launch_job (job *j, int foreground)
 process *p;
 pid_t pid;
  int mypipe[2], infile, outfile;
  infile = j->stdin;
  for (p = j->first_process; p; p = p->next)
      /* Set up pipes, if necessary. */
      if (p->next)
          if (pipe (mypipe) < 0)
              perror ("pipe");
              exit (1);
          outfile = mypipe[1];
        }
      else
        outfile = j->stdout;
```

```
/* Fork the child processes. */
      pid = fork ();
      if (pid == 0)
        /* This is the child process. */
        launch_process (p, j->pgid, infile, outfile, j->stderr, foreground);
      else if (pid < 0)
        {
          /* The fork failed.
          perror ("fork");
          exit (1);
      else
        {
          /* This is the parent process. */
          p->pid = pid;
          if (shell_is_interactive)
               if (!j->pgid)
                 j->pgid = pid;
               setpgid (pid, j->pgid);
        }
      /* Clean up after pipes. */
      if (infile != j->stdin)
        close (infile);
      if (outfile != j->stdout)
        close (outfile);
      infile = mypipe[0];
    }
  format_job_info (j, "launched");
  if (!shell_is_interactive)
    wait_for_job (j);
  else if (foreground)
    put_job_in_foreground (j, 0);
    put_job_in_background (j, 0);
}
```

24.6.4 Foreground and Background

Now let's consider what actions must be taken by the shell when it launches a job into the foreground, and how this differs from what must be done when a background job is launched.

When a foreground job is launched, the shell must first give it access to the controlling terminal by calling tcsetpgrp. Then, the shell should wait for processes in that process group to terminate or stop. This is discussed in more detail in Section 24.6.5 [Stopped and Terminated Jobs], page 509.

When all of the processes in the group have either completed or stopped, the shell should regain control of the terminal for its own process group by calling tcsetpgrp again. Since stop signals caused by I/O from a background process or a SUSP character typed by the user are sent to the process group, normally all the processes in the job stop together.

The foreground job may have left the terminal in a strange state, so the shell should restore its own saved terminal modes before continuing. In case the job is merely been stopped, the shell should first save the current terminal modes so that it can restore them later if the job is continued. The functions for dealing with terminal modes are tcgetattr and tcsetattr; these are described in Section 16.4 [Terminal Modes], page 323.

Here is the sample shell's function for doing all of this.

```
/* Put job j in the foreground. If cont is nonzero,
   restore the saved terminal modes and send the process group a
   SIGCONT signal to wake it up before we block. */
void
put_job_in_foreground (job *j, int cont)
{
  /* Put the job into the foreground. */
  tcsetpgrp (shell_terminal, j->pgid);
  /* Send the job a continue signal, if necessary. */
  if (cont)
    {
      tcsetattr (shell_terminal, TCSADRAIN, &j->tmodes);
      if (kill (- j->pgid, SIGCONT) < 0)
        perror ("kill (SIGCONT)");
    }
  /* Wait for it to report. */
  wait_for_job (j);
  /* Put the shell back in the foreground.
  tcsetpgrp (shell_terminal, shell_pgid);
```

```
/* Restore the shell's terminal modes. */
tcgetattr (shell_terminal, &j->tmodes);
tcsetattr (shell_terminal, TCSADRAIN, &shell_tmodes);
}
```

If the process group is launched as a background job, the shell should remain in the foreground itself and continue to read commands from the terminal.

In the sample shell, there is not much that needs to be done to put a job into the background. Here is the function it uses:

```
/* Put a job in the background. If the cont argument is true, send
    the process group a SIGCONT signal to wake it up. */

void
put_job_in_background (job *j, int cont)
{
    /* Send the job a continue signal, if necessary. */
    if (cont)
        if (kill (-j->pgid, SIGCONT) < 0)
            perror ("kill (SIGCONT)");
}</pre>
```

24.6.5 Stopped and Terminated Jobs

When a foreground process is launched, the shell must block until all of the processes in that job have either terminated or stopped. It can do this by calling the waitpid function; see Section 23.6 [Process Completion], page 488. Use the WUNTRACED option so that status is reported for processes that stop as well as processes that terminate.

The shell must also check on the status of background jobs so that it can report terminated and stopped jobs to the user; this can be done by calling waitpid with the WNOHANG option. A good place to put a such a check for terminated and stopped jobs is just before prompting for a new command.

The shell can also receive asynchronous notification that there is status information available for a child process by establishing a handler for SIGCHLD signals. See Chapter 21 [Signal Handling], page 403.

In the sample shell program, the SIGCHLD signal is normally ignored. This is to avoid reentrancy problems involving the global data structures the shell manipulates. But at specific times when the shell is not using these data structures—such as when it is waiting for input on the terminal—it makes sense to enable a handler for SIGCHLD. The same function that is used to do the synchronous status checks (do_job_notification, in this case) can also be called from within this handler.

Here are the parts of the sample shell program that deal with checking the status of jobs and reporting the information to the user.

```
/* Store the status of the process pid that was returned by waitpid.
    Return 0 if all went well, nonzero otherwise. */
int
mark_process_status (pid_t pid, int status)
{
    job *j;
    process *p;
```

```
if (pid > 0)
    {
      /* Update the record for the process. */
      for (j = first_job; j; j = j->next)
        for (p = j->first_process; p; p = p->next)
          if (p->pid == pid)
            {
              p->status = status;
              if (WIFSTOPPED (status))
                p->stopped = 1;
              else
                {
                  p->completed = 1;
                   if (WIFSIGNALED (status))
                    fprintf (stderr, "%d: Terminated by signal %d.\n",
                              (int) pid, WTERMSIG (p->status));
                }
              return 0;
             }
      fprintf (stderr, "No child process %d.\n", pid);
      return -1;
    }
  else if (pid == 0 || errno == ECHILD)
    /* No processes ready to report. */
    return -1;
  else {
    /* Other weird errors. */
    perror ("waitpid");
    return -1;
  }
}
```

```
/* Check for processes that have status information available,
   without blocking. */
void
update_status (void)
{
  int status;
  pid_t pid;
  do
    pid = waitpid (WAIT_ANY, &status, WUNTRACED|WNOHANG);
  while (!mark_process_status (pid, status));
}
/* Check for processes that have status information available,
   blocking until all processes in the given job have reported. */
void
wait_for_job (job *j)
{
  int status;
  pid_t pid;
  do
    pid = waitpid (WAIT_ANY, &status, WUNTRACED);
  while (!mark_process_status (pid, status)
         && !job_is_stopped (j)
         && !job_is_completed (j));
}
/* Format information about job status for the user to look at. */
void
format_job_info (job *j, const char *status)
{
  fprintf (stderr, "%ld (%s): %s\n", (long)j->pgid, status, j->command);
}
```

```
/* Notify the user about stopped or terminated jobs.
   Delete terminated jobs from the active job list. */
void
do_job_notification (void)
{
  job *j, *jlast, *jnext;
  process *p;
  /* Update status information for child processes. */
  update_status ();
  jlast = NULL;
  for (j = first_job; j; j = jnext)
      jnext = j->next;
      /* If all processes have completed, tell the user the job has
          completed and delete it from the list of active jobs. */
      if (job_is_completed (j)) {
         format_job_info (j, "completed");
         if (jlast)
           jlast->next = jnext;
         else
           first_job = jnext;
         free_job (j);
      /* Notify the user about stopped jobs,
          marking them so that we won't do this more than once. */
      else if (job_is_stopped (j) && !j->notified) {
         format_job_info (j, "stopped");
         j->notified = 1;
         jlast = j;
      }
      /* Don't say anything about jobs that are still running. */
      else
         jlast = j;
    }
}
```

24.6.6 Continuing Stopped Jobs

The shell can continue a stopped job by sending a SIGCONT signal to its process group. If the job is being continued in the foreground, the shell should first invoke tcsetpgrp to give the job access to the terminal, and restore the saved terminal settings. After continuing a job in the foreground, the shell should wait for the job to stop or complete, as if the job had just been launched in the foreground.

The sample shell program uses the same set of functions—put_job_in_foreground and put_job_in_background—to handle both newly created and continued jobs. The definitions of these functions were given in Section 24.6.4 [Foreground and Background], page 507. When continuing a stopped job, a nonzero value is passed as the *cont* argument to ensure that the SIGCONT signal is sent and the terminal modes reset, as appropriate.

This leaves only a function for updating the shell's internal bookkeeping about the job being continued:

```
/* Mark a stopped job J as being running again. */
void
mark_job_as_running (job *j)
{
  Process *p;
  for (p = j->first_process; p; p = p->next)
    p->stopped = 0;
  j-notified = 0;
/* Continue the job J. */
continue_job (job *j, int foreground)
{
  mark_job_as_running (j);
  if (foreground)
    put_job_in_foreground (j, 1);
  else
    put_job_in_background (j, 1);
}
```

24.6.7 The Missing Pieces

The code extracts for the sample shell included in this chapter are only a part of the entire shell program. In particular, nothing at all has been said about how job and program data structures are allocated and initialized.

Most real shells provide a complex user interface that has support for a command language; variables; abbreviations, substitutions, and pattern matching on file names; and the like. All of this is far too complicated to explain here! Instead, we have concentrated on showing how to implement the core process creation and job control functions that can be called from such a shell.

Here is a table summarizing the major entry points we have presented:

void init_shell (void)

Initialize the shell's internal state. See Section 24.6.2 [Initializing the Shell], page 501.

void launch_job (job *j, int foreground)

Launch the job j as either a foreground or background job. See Section 24.6.3 [Launching Jobs], page 503.

void do_job_notification (void)

Check for and report any jobs that have terminated or stopped. Can be called synchronously or within a handler for SIGCHLD signals. See Section 24.6.5 [Stopped and Terminated Jobs], page 509.

void continue_job (job *j, int foreground)

Continue the job j. See Section 24.6.6 [Continuing Stopped Jobs], page 514.

Of course, a real shell would also want to provide other functions for managing jobs. For example, it would be useful to have commands to list all active jobs or to send a signal (such as SIGKILL) to a job.

24.7 Functions for Job Control

This section contains detailed descriptions of the functions relating to job control.

24.7.1 Identifying the Controlling Terminal

You can use the ctermid function to get a file name that you can use to open the controlling terminal. In the GNU library, it returns the same string all the time: "/dev/tty". That is a special "magic" file name that refers to the controlling terminal of the current process (if it has one). The function ctermid is declared in the header file 'stdio.h'.

char * ctermid (char *string)

Function

The ctermid function returns a string containing the file name of the controlling terminal for the current process. If *string* is not a null pointer, it should be an array that can hold at least L_ctermid characters; the string is returned in this array. Otherwise, a pointer to a string in a static area is returned, which might get overwritten on subsequent calls to this function.

An empty string is returned if the file name cannot be determined for any reason. Even if a file name is returned, access to the file it represents is not guaranteed.

int L_ctermid Macro

The value of this macro is an integer constant expression that represents the size of a string large enough to hold the file name returned by ctermid.

See also the isatty and ttyname functions, in Section 16.1 [Is It a Terminal], page 321.

24.7.2 Process Group Functions

Here are descriptions of the functions for manipulating process groups. Your program should include the header files 'sys/types.h' and 'unistd.h' to use these functions.

pid_t setsid (void)

Function

The setsid function creates a new session. The calling process becomes the session leader, and is put in a new process group whose process group ID is the same as the process ID of that process. There are initially no other processes in the new process group, and no other process groups in the new session.

This function also makes the calling process have no controlling terminal.

The setsid function returns the new process group ID of the calling process if successful. A return value of -1 indicates an error. The following error conditions are defined for this function:

EPERM The calling process is already a process group leader, or there is already another process group around that has the same process group ID.

The getpgrp function has two definitions: one derived from BSD Unix, and one from the POSIX.1 standard. The feature test macros you have selected (see Section 1.3.4 [Feature Test Macros], page 9) determine which definition you get. Specifically, you get the BSD version if you define _BSD_SOURCE; otherwise, you get the POSIX version if you define _POSIX_SOURCE or _GNU_SOURCE. Programs written for old BSD systems will not include 'unistd.h', which defines getpgrp specially under _BSD_SOURCE. You must link such programs with the -lbsd-compat option to get the BSD definition.

pid_t getpgrp (void)

POSIX.1 Function

The POSIX.1 definition of getpgrp returns the process group ID of the calling process.

pid_t getpgrp (pid_t pid)

BSD Function

The BSD definition of **getpgrp** returns the process group ID of the process *pid*. You can supply a value of 0 for the *pid* argument to get information about the calling process.

int setpgid (pid_t pid, pid_t pgid)

Function

The **setpgid** function puts the process *pid* into the process group *pgid*. As a special case, either *pid* or *pgid* can be zero to indicate the process ID of the calling process.

This function fails on a system that does not support job control. See Section 24.2 [Job Control is Optional], page 496, for more information.

If the operation is successful, setpgid returns zero. Otherwise it returns -1. The following errno error conditions are defined for this function:

EACCES The child process named by *pid* has executed an exec function since it was forked.

EINVAL The value of the pgid is not valid.

ENOSYS The system doesn't support job control.

EPERM The process indicated by the pid argument is a session leader, or is not in

the same session as the calling process, or the value of the *pgid* argument doesn't match a process group ID in the same session as the calling process.

ESRCH The process indicated by the pid argument is not the calling process or a

child of the calling process.

int setpgrp (pid_t pid, pid_t pgid)

Function

This is the BSD Unix name for setpgid. Both functions do exactly the same thing.

24.7.3 Functions for Controlling Terminal Access

These are the functions for reading or setting the foreground process group of a terminal. You should include the header files 'sys/types.h' and 'unistd.h' in your application to use these functions.

Although these functions take a file descriptor argument to specify the terminal device, the foreground job is associated with the terminal file itself and not a particular open file descriptor.

pid_t tcgetpgrp (int filedes)

Function

This function returns the process group ID of the foreground process group associated with the terminal open on descriptor filedes.

If there is no foreground process group, the return value is a number greater than 1 that does not match the process group ID of any existing process group. This can happen if all of the processes in the job that was formerly the foreground job have terminated, and no other job has yet been moved into the foreground.

In case of an error, a value of -1 is returned. The following error conditions are defined for this function:

EBADF The filedes argument is not a valid file descriptor.

ENOSYS The system doesn't support job control.

ENOTTY The terminal file associated with the filedes argument isn't the controlling

terminal of the calling process.

int tcsetpgrp (int filedes, pid_t pgid)

Function

This function is used to set a terminal's foreground process group ID. The argument filedes is a descriptor which specifies the terminal; pgid specifies the process group. The calling process must be a member of the same session as pgid and must have the same controlling terminal.

For terminal access purposes, this function is treated as output. If it is called from a background process on its controlling terminal, normally all processes in the process group are sent a SIGTTOU signal. The exception is if the calling process itself is ignoring or blocking SIGTTOU signals, in which case the operation is performed and no signal is sent.

If successful, tcsetpgrp returns 0. A return value of -1 indicates an error. The following error conditions are defined for this function:

EBADF The filedes argument is not a valid file descriptor.

EINVAL The pgid argument is not valid.

ENOSYS The system doesn't support job control.

ENOTTY The filedes isn't the controlling terminal of the calling process.

EPERM The pgid isn't a process group in the same session as the calling process.

520

25 Users and Groups

Every user who can log in on the system is identified by a unique number called the *user ID*. Each process has an effective user ID which says which user's access permissions it has.

Users are classified into *groups* for access control purposes. Each process has one or more *group* ID values which say which groups the process can use for access to files.

The effective user and group IDs of a process collectively form its *persona*. This determines which files the process can access. Normally, a process inherits its persona from the parent process, but under special circumstances a process can change its persona and thus change its access permissions.

Each file in the system also has a user ID and a group ID. Access control works by comparing the user and group IDs of the file with those of the running process.

The system keeps a database of all the registered users, and another database of all the defined groups. There are library functions you can use to examine these databases.

25.1 User and Group IDs

Each user account on a computer system is identified by a user name (or login name) and user ID. Normally, each user name has a unique user ID, but it is possible for several login names to have the same user ID. The user names and corresponding user IDs are stored in a data base which you can access as described in Section 25.12 [User Database], page 533.

Users are classified in *groups*. Each user name also belongs to one or more groups, and has one default group. Users who are members of the same group can share resources (such as files) that are not accessible to users who are not a member of that group. Each group has a group name and group ID. See Section 25.13 [Group Database], page 536, for how to find information about a group ID or group name.

25.2 The Persona of a Process

At any time, each process has a single user ID and a group ID which determine the privileges of the process. These are collectively called the *persona* of the process, because they determine "who 522 The GNU C Library

it is" for purposes of access control. These IDs are also called the effective user ID and effective group ID of the process.

Your login shell starts out with a persona which consists of your user ID and your default group ID. In normal circumstances, all your other processes inherit these values.

A process also has a real user ID which identifies the user who created the process, and a real group ID which identifies that user's default group. These values do not play a role in access control, so we do not consider them part of the persona. But they are also important.

Both the real and effective user ID can be changed during the lifetime of a process. See Section 25.3 [Why Change Persona], page 522.

In addition, a user can belong to multiple groups, so the persona includes supplementary group IDs that also contribute to access permission.

For details on how a process's effective user IDs and group IDs affect its permission to access files, see Section 13.8.6 [Access Permission], page 255.

The user ID of a process also controls permissions for sending signals using the kill function. See Section 21.6.2 [Signaling Another Process], page 441.

25.3 Why Change the Persona of a Process?

The most obvious situation where it is necessary for a process to change its user and/or group IDs is the login program. When login starts running, its user ID is root. Its job is to start a shell whose user and group IDs are those of the user who is logging in. (To accomplish this fully, login must set the real user and group IDs as well as its persona. But this is a special case.)

The more common case of changing persona is when an ordinary user program needs access to a resource that wouldn't ordinarily be accessible to the user actually running it.

For example, you may have a file that is controlled by your program but that shouldn't be read or modified directly by other users, either because it implements some kind of locking protocol, or because you want to preserve the integrity or privacy of the information it contains. This kind of restricted access can be implemented by having the program change its effective user or group ID to match that of the resource.

Thus, imagine a game program that saves scores in a file. The game program itself needs to be able to update this file no matter who is running it, but if users can write the file without going through the game, they can give themselves any scores they like. Some people consider this undesirable, or even reprehensible. It can be prevented by creating a new user ID and login name (say, games) to own the scores file, and make the file writable only by this user. Then, when the game program wants to update this file, it can change its effective user ID to be that for games. In effect, the program must adopt the persona of games so it can write the scores file.

25.4 How an Application Can Change Persona

The ability to change the persona of a process can be a source of unintentional privacy violations, or even intentional abuse. Because of the potential for problems, changing persona is restricted to special circumstances.

You can't arbitrarily set your user ID or group ID to anything you want; only privileged processes can do that. Instead, the normal way for a program to change its persona is that it has been set up in advance to change to a particular user or group. This is the function of the setuid and setgid bits of a file's access mode. See Section 13.8.5 [Permission Bits], page 253.

When the setuid bit of an executable file is set, executing that file automatically changes the effective user ID to the user that owns the file. Likewise, executing a file whose setgid bit is set changes the effective group ID to the group of the file. See Section 23.5 [Executing a File], page 485. Creating a file that changes to a particular user or group ID thus requires full access to that user or group ID.

See Section 13.8 [File Attributes], page 246, for a more general discussion of file modes and accessibility.

A process can always change its effective user (or group) ID back to its real ID. Programs do this so as to turn off their special privileges when they are not needed, which makes for more robustness.

25.5 Reading the Persona of a Process

Here are detailed descriptions of the functions for reading the user and group IDs of a process, both real and effective. To use these facilities, you must include the header files 'sys/types.h' and 'unistd.h'.

 $\mathbf{uid_t}$ Data Type

This is an integer data type used to represent user IDs. In the GNU library, this is an alias for unsigned int.

gid_t Data Type

This is an integer data type used to represent group IDs. In the GNU library, this is an alias for unsigned int.

uid_t getuid (void)

Function

The getuid function returns the real user ID of the process.

gid_t getgid (void)

Function

The getgid function returns the real group ID of the process.

uid_t geteuid (void)

Function

The geteuid function returns the effective user ID of the process.

gid_t getegid (void)

Function

The getegid function returns the effective group ID of the process.

int getgroups (int count, gid_t *groups)

Function

The getgroups function is used to inquire about the supplementary group IDs of the process. Up to *count* of these group IDs are stored in the array *groups*; the return value from the function is the number of group IDs actually stored. If *count* is smaller than the total number of supplementary group IDs, then getgroups returns a value of -1 and errno is set to EINVAL.

If *count* is zero, then **getgroups** just returns the total number of supplementary group IDs. On systems that do not support supplementary groups, this will always be zero.

Here's how to use getgroups to read all the supplementary group IDs:

```
gid_t *
read_all_groups (void)
{
  int ngroups = getgroups (NULL, 0);
  gid_t *groups = (gid_t *) xmalloc (ngroups * sizeof (gid_t));
  int val = getgroups (ngroups, groups);
  if (val < 0)
    {
     free (groups);
     return NULL;
    }
  return groups;
}</pre>
```

25.6 Setting the User ID

This section describes the functions for altering the user ID (real and/or effective) of a process. To use these facilities, you must include the header files 'sys/types.h' and 'unistd.h'.

```
int setuid (uid_t newuid)
```

Function

This function sets both the real and effective user ID of the process to newuid, provided that the process has appropriate privileges.

If the process is not privileged, then *newuid* must either be equal to the real user ID or the saved user ID (if the system supports the <code>_POSIX_SAVED_IDS</code> feature). In this case, <code>setuid</code> sets only the effective user ID and not the real user ID.

The setuid function returns a value of 0 to indicate successful completion, and a value of -1 to indicate an error. The following error conditions are defined for this function:

EINVAL The value of the newuid argument is invalid.

EPERM The process does not have the appropriate privileges; you do not have permission to change to the specified ID.

int setreuid (uid_t ruid, uid_t euid)

Function

This function sets the real user ID of the process to *ruid* and the effective user ID to euid.

The setreuid function exists for compatibility with 4.3 BSD Unix, which does not support saved IDs. You can use this function to swap the effective and real user IDs of the process. (Privileged processes are not limited to this particular usage.) If saved IDs are supported, you should use that feature instead of this function. See Section 25.8 [Enable/Disable Setuid], page 527.

The return value is 0 on success and -1 on failure. The following errno error conditions are defined for this function:

EPERM The process does not have the appropriate privileges; you do not have permission to change to the specified ID.

25.7 Setting the Group IDs

This section describes the functions for altering the group IDs (real and effective) of a process. To use these facilities, you must include the header files 'sys/types.h' and 'unistd.h'.

int setgid (gid_t newgid)

Function

This function sets both the real and effective group ID of the process to newgid, provided that the process has appropriate privileges.

If the process is not privileged, then newgid must either be equal to the real group ID or the saved group ID. In this case, setgid sets only the effective group ID and not the real group ID.

The return values and error conditions for setgid are the same as those for setuid.

int setregid (gid_t rgid, fid_t egid)

Function

This function sets the real group ID of the process to rgid and the effective group ID to egid.

The setregid function is provided for compatibility with 4.3 BSD Unix, which does not support saved IDs. You can use this function to swap the effective and real group

IDs of the process. (Privileged processes are not limited to this usage.) If saved IDs are supported, you should use that feature instead of using this function. See Section 25.8 [Enable/Disable Setuid], page 527.

The return values and error conditions for setregid are the same as those for setreuid.

The GNU system also lets privileged processes change their supplementary group IDs. To use setgroups or initgroups, your programs should include the header file 'grp.h'.

```
int setgroups (size_t count, gid_t *groups)
```

Function

This function sets the process's supplementary group IDs. It can only be called from privileged processes. The *count* argument specifies the number of group IDs in the array groups.

This function returns 0 if successful and -1 on error. The following errno error conditions are defined for this function:

EPERM The calling process is not privileged.

```
int initgroups (const char *user, gid_t gid)
```

Function

The initgroups function effectively calls setgroups to set the process's supplementary group IDs to be the normal default for the user name user. The group ID gid is also included.

25.8 Enabling and Disabling Setuid Access

A typical setuid program does not need its special access all of the time. It's a good idea to turn off this access when it isn't needed, so it can't possibly give unintended access.

If the system supports the saved user ID feature, you can accomplish this with setuid. When the game program starts, its real user ID is jdoe, its effective user ID is games, and its saved user ID is also games. The program should record both user ID values once at the beginning, like this:

```
user_user_id = getuid ();
game_user_id = geteuid ();
```

Then it can turn off game file access with

```
setuid (user_user_id);
```

and turn it on with

```
setuid (game_user_id);
```

Throughout this process, the real user ID remains jdoe and the saved user ID remains games, so the program can always set its effective user ID to either one.

On other systems that don't support the saved user ID feature, you can turn setuid access on and off by using setreuid to swap the real and effective user IDs of the process, as follows:

```
setreuid (geteuid (), getuid ());
```

This special case is always allowed—it cannot fail.

Why does this have the effect of toggling the setuid access? Suppose a game program has just started, and its real user ID is jdoe while its effective user ID is games. In this state, the game can write the scores file. If it swaps the two uids, the real becomes games and the effective becomes jdoe; now the program has only jdoe access. Another swap brings games back to the effective user ID and restores access to the scores file.

In order to handle both kinds of systems, test for the saved user ID feature with a preprocessor conditional, like this:

```
#ifdef _POSIX_SAVED_IDS
   setuid (user_user_id);
#else
   setreuid (geteuid (), getuid ());
#endif
```

25.9 Setuid Program Example

Here's an example showing how to set up a program that changes its effective user ID.

This is part of a game program called caber-toss that manipulates a file 'scores' that should be writable only by the game program itself. The program assumes that its executable file will be installed with the set-user-ID bit set and owned by the same user as the 'scores' file. Typically, a system administrator will set up an account like games for this purpose.

The executable file is given mode 4755, so that doing an 'ls -l' on it produces output like:

```
-rwsr-xr-x 1 games 184422 Jul 30 15:17 caber-toss
```

The set-user-ID bit shows up in the file modes as the 's'.

The scores file is given mode 644, and doing an '1s -1' on it shows:

```
-rw-r--r-- 1 games 0 Jul 31 15:33 scores
```

Here are the parts of the program that show how to set up the changed user ID. This program is conditionalized so that it makes use of the saved IDs feature if it is supported, and otherwise uses setreuid to swap the effective and real user IDs.

```
#include <stdio.h>
#include <sys/types.h>
#include <unistd.h>
#include <stdlib.h>

/* Save the effective and real UIDs. */
static uid_t euid, ruid;

/* Restore the effective UID to its original value. */
void
do_setuid (void)
```

```
{
  int status;
#ifdef _POSIX_SAVED_IDS
  status = setuid (euid);
#else
  status = setreuid (ruid, euid);
#endif
  if (status < 0) {
    fprintf (stderr, "Couldn't set uid.\n");
    exit (status);
}
/* Set the effective UID to the real UID. */
void
undo_setuid (void)
{
  int status;
#ifdef _POSIX_SAVED_IDS
  status = setuid (ruid);
  status = setreuid (euid, ruid);
#endif
  if (status < 0) {</pre>
    fprintf (stderr, "Couldn't set uid.\n");
    exit (status);
    }
}
/* Main program. */
int
main (void)
  /* Save the real and effective user IDs. */
  ruid = getuid ();
  euid = geteuid ();
  undo_setuid ();
  /* Do the game and record the score. */
}
```

Notice how the first thing the main function does is to set the effective user ID back to the real user ID. This is so that any other file accesses that are performed while the user is playing the game use the real user ID for determining permissions. Only when the program needs to open the scores file does it switch back to the original effective user ID, like this:

```
/* Record the score. */
record_score (int score)
  FILE *stream;
  char *myname;
  /* Open the scores file. */
  do_setuid ();
  stream = fopen (SCORES_FILE, "a");
  undo_setuid ();
  /* Write the score to the file. */
  if (stream)
    {
      myname = cuserid (NULL);
      if (score < 0)
        fprintf (stream, "%10s: Couldn't lift the caber.\n", myname);
      else
        fprintf (stream, "%10s: %d feet.\n", myname, score);
      fclose (stream);
      return 0;
    }
  else
    return -1;
}
```

25.10 Tips for Writing Setuid Programs

It is easy for setuid programs to give the user access that isn't intended—in fact, if you want to avoid this, you need to be careful. Here are some guidelines for preventing unintended access and minimizing its consequences when it does occur:

- Don't have setuid programs with privileged user IDs such as root unless it is absolutely necessary. If the resource is specific to your particular program, it's better to define a new, nonprivileged user ID or group ID just to manage that resource.
- Be cautious about using the system and exec functions in combination with changing the effective user ID. Don't let users of your program execute arbitrary programs under a changed user ID. Executing a shell is especially bad news. Less obviously, the execlp and execvp functions are a potential risk (since the program they execute depends on the user's PATH environment variable).
 - If you must exec another program under a changed ID, specify an absolute file name (see Section 10.2.2 [File Name Resolution], page 135) for the executable, and make sure that the protections on that executable and all containing directories are such that ordinary users cannot replace it with some other program.
- Only use the user ID controlling the resource in the part of the program that actually uses that resource. When you're finished with it, restore the effective user ID back to the actual user's user ID. See Section 25.8 [Enable/Disable Setuid], page 527.
- If the setuid part of your program needs to access other files besides the controlled resource, it should verify that the real user would ordinarily have permission to access those files. You can use the access function (see Section 13.8.6 [Access Permission], page 255) to check this; it uses the real user and group IDs, rather than the effective IDs.

25.11 Identifying Who Logged In

You can use the functions listed in this section to determine the login name of the user who is running a process, and the name of the user who logged in the current session. See also the function getuid and friends (see Section 25.5 [Reading Persona], page 523).

The getlogin function is declared in 'unistd.h', while cuserid and L_cuserid are declared in 'stdio.h'.

char * getlogin (void)

Function

The getlogin function returns a pointer to a string containing the name of the user logged in on the controlling terminal of the process, or a null pointer if this information cannot be determined. The string is statically allocated and might be overwritten on subsequent calls to this function or to cuserid.

char * cuserid (char *string)

Function

The cuserid function returns a pointer to a string containing a user name associated with the effective ID of the process. If string is not a null pointer, it should be an array that can hold at least L_cuserid characters; the string is returned in this array. Otherwise, a pointer to a string in a static area is returned. This string is statically allocated and might be overwritten on subsequent calls to this function or to getlogin.

int L_cuserid Macro

An integer constant that indicates how long an array you might need to store a user name.

These functions let your program identify positively the user who is running or the user who logged in this session. (These can differ when setuid programs are involved; See Section 25.2 [Process Persona], page 521.) The user cannot do anything to fool these functions.

For most purposes, it is more useful to use the environment variable LOGNAME to find out who the user is. This is more flexible precisely because the user can set LOGNAME arbitrarily. See Section 22.2.2 [Standard Environment], page 474.

25.12 User Database

This section describes all about now to search and scan the database of registered users. The database itself is kept in the file '/etc/passwd' on most systems, but on some systems a special network server gives access to it.

25.12.1 The Data Structure that Describes a User

The functions and data structures for accessing the system user database are declared in the header file 'pwd.h'.

struct passwd Data Type

The passwd data structure is used to hold information about entries in the system user data base. It has at least the following members:

char *pw_name

The user's login name.

char *pw_passwd.

The encrypted password string.

uid_t pw_uid

The user ID number.

gid_t pw_gid

The user's default group ID number.

char *pw_gecos

A string typically containing the user's real name, and possibly other information such as a phone number.

char *pw_dir

The user's home directory, or initial working directory. This might be a null pointer, in which case the interpretation is system-dependent.

char *pw_shell

The user's default shell, or the initial program run when the user logs in. This might be a null pointer, indicating that the system default should be used.

25.12.2 Looking Up One User

You can search the system user database for information about a specific user using getpwuid or getpwnam. These functions are declared in 'pwd.h'.

struct passwd * getpwuid (uid_t uid)

Function

This function returns a pointer to a statically-allocated structure containing information about the user whose user ID is uid. This structure may be overwritten on subsequent calls to getpwuid.

A null pointer value indicates there is no user in the data base with user ID uid.

struct passwd * getpwnam (const char *name)

Function

This function returns a pointer to a statically-allocated structure containing information about the user whose user name is *name*. This structure may be overwritten on subsequent calls to getpwnam.

A null pointer value indicates there is no user named name.

25.12.3 Scanning the List of All Users

This section explains how a program can read the list of all users in the system, one user at a time. The functions described here are declared in 'pwd.h'.

The recommended way to scan the users is to open the user file and then call **fgetpwent** for each successive user:

struct passwd * fgetpwent (FILE *stream)

Function

This function reads the next user entry from *stream* and returns a pointer to the entry. The structure is statically allocated and is rewritten on subsequent calls to **getpwent**. You must copy the contents of the structure if you wish to save the information.

This stream must correspond to a file in the same format as the standard password database file. This function comes from System V.

Another way to scan all the entries in the group database is with setpwent, getpwent, and endpwent. But this method is less robust than fgetpwent, so we provide it only for compatibility with SVID. In particular, these functions are not reentrant and are not suitable for use in programs with multiple threads of control.

void setpwent (void)

Function

This function initializes a stream which getpwent uses to read the user database.

struct passwd * getpwent (void)

Function

The getpwent function reads the next entry from the stream initialized by setpwent. It returns a pointer to the entry. The structure is statically allocated and is rewritten on subsequent calls to getpwent. You must copy the contents of the structure if you wish to save the information.

void endpwent (void)

Function

This function closes the internal stream used by getpwent.

25.12.4 Writing a User Entry

int putpwent (const struct passwd *p, FILE *stream)

Function

This function writes the user entry *p to the stream stream, in the format used for the standard user database file. The return value is zero on success and nonzero on failure.

This function exists for compatibility with SVID. We recommend that you avoid using it, because it makes sense only on the assumption that the struct passwd structure has no members except the standard ones; on a system which merges the traditional Unix data base with other extended information about users, adding an entry using this function would inevitably leave out much of the important information.

The function putpwent is declared in 'pwd.h'.

25.13 Group Database

This section describes all about how to search and scan the database of registered groups. The database itself is kept in the file '/etc/group' on most systems, but on some systems a special network service provides access to it.

25.13.1 The Data Structure for a Group

The functions and data structures for accessing the system group database are declared in the header file 'grp.h'.

struct group Data Type

The group structure is used to hold information about an entry in the system group database. It has at least the following members:

char *gr_name

The name of the group.

gid_t gr_gid

The group ID of the group.

char **gr_mem

A vector of pointers to the names of users in the group. Each user name is a null-terminated string, and the vector itself is terminated by a null pointer.

25.13.2 Looking Up One Group

You can search the group database for information about a specific group using getgrgid or getgrnam. These functions are declared in 'grp.h'.

struct group * getgrgid (gid_t gid)

Function

This function returns a pointer to a statically-allocated structure containing information about the group whose group ID is gid. This structure may be overwritten by subsequent calls to getgrgid.

A null pointer indicates there is no group with ID gid.

struct group * getgrnam (const char *name)

Function

This function returns a pointer to a statically-allocated structure containing information about the group whose group name is *name*. This structure may be overwritten by subsequent calls to getgrnam.

A null pointer indicates there is no group named name.

25.13.3 Scanning the List of All Groups

This section explains how a program can read the list of all groups in the system, one group at a time. The functions described here are declared in 'grp.h'.

The recommended way to scan the groups is to open the group file and then call **fgetgrent** for each successive group:

struct group * fgetgrent (FILE *stream)

Function

The fgetgrent function reads the next entry from *stream*. It returns a pointer to the entry. The structure is statically allocated and is rewritten on subsequent calls to getgrent. You must copy the contents of the structure if you wish to save the information.

The stream must correspond to a file in the same format as the standard group database file.

Another way to scan all the entries in the group database is with setgrent, getgrent, and endgrent. But this method is less robust than fgetgrent, so we provide it only for compatibility with SVID. In particular, these functions are not reentrant and are not suitable for use in programs with multiple threads of control.

void setgrent (void)

Function

This function initializes a stream for reading from the group data base. You use this stream by calling getgrent.

```
struct group * getgrent (void)
```

Function

The getgrent function reads the next entry from the stream initialized by setgrent. It returns a pointer to the entry. The structure is statically allocated and is rewritten on subsequent calls to getgrent. You must copy the contents of the structure if you wish to save the information.

```
void endgrent (void)
```

Function

This function closes the internal stream used by getgrent.

25.14 User and Group Database Example

Here is an example program showing the use of the system database inquiry functions. The program prints some information about the user running the program.

```
#include <grp.h>
#include <pwd.h>
#include <sys/types.h>
#include <unistd.h>
#include <stdlib.h>

int
main (void)
{
   uid_t me;
   struct passwd *my_passwd;
   struct group *my_group;
   char **members;
```

```
/* Get information about the user ID. */
  me = getuid ();
  my_passwd = getpwuid (me);
  if (!my_passwd)
      printf ("Couldn't find out about user %d.\n", (int) me);
      exit (EXIT_FAILURE);
  /* Print the information. */
 printf ("I am %s.\n", my_passwd->pw_gecos);
  printf ("My login name is %s.\n", my_passwd->pw_name);
  printf ("My uid is %d.\n", (int) (my_passwd->pw_uid));
 printf ("My home directory is %s.\n", my_passwd->pw_dir);
 printf ("My default shell is %s.\n", my_passwd->pw_shell);
  /* Get information about the default group ID. */
  my_group = getgrgid (my_passwd->pw_gid);
  if (!my_group)
    {
     printf ("Couldn't find out about group %d.\n", (int) my_passwd->pw_gid);
      exit (EXIT_FAILURE);
  /* Print the information. */
 printf ("My default group is %s (%d).\n",
  my_group->gr_name, (int) (my_passwd->pw_gid));
  printf ("The members of this group are:\n");
 members = my_group->gr_mem;
  while (*members)
    {
      printf (" %s\n", *(members));
      members++;
 return EXIT_SUCCESS;
}
```

Here is some output from this program:

```
I am Throckmorton Snurd.
My login name is snurd.
My uid is 31093.
My home directory is /home/fsg/snurd.
My default shell is /bin/sh.
My default group is guest (12).
```

540 The GNU C Library

The members of this group are: friedman tami

26 System Information

This chapter describes functions that return information about the particular machine that is in use—the type of hardware, the type of software, and the individual machine's name.

26.1 Host Identification

This section explains how to identify the particular machine that your program is running on. The identification of a machine consists of its Internet host name and Internet address; see Section 15.5 [Internet Namespace], page 278.

Prototypes for these functions appear in 'unistd.h'. The shell commands hostname and hostid work by calling them.

int gethostname (char *name, size_t size)

Function

This function returns the name of the host machine in the array name. The size argument specifies the size of this array, in bytes.

The return value is 0 on success and -1 on failure. In the GNU C library, gethostname fails if size is not large enough; then you can try again with a larger array. The following errno error condition is defined for this function:

ENAMETOOLONG

The size argument is less than the size of the host name plus one.

On some systems, there is a symbol for the maximum possible host name length: MAXHOSTNAMELEN. It is defined in 'sys/param.h'. But you can't count on this to exist, so it is cleaner to handle failure and try again.

gethostname stores the beginning of the host name in name even if the host name won't entirely fit. For some purposes, a truncated host name is good enough. If it is, you can ignore the error code.

int sethostname (const char *name, size_t length)

Function

The sethostname function sets the name of the host machine to name, a string with length length. Only privileged processes are allowed to do this. Usually it happens just once, at system boot time.

The return value is 0 on success and -1 on failure. The following errno error condition is defined for this function:

EPERM This process cannot set the host name because it is not privileged.

long int gethostid (void)

Function

This function returns the Internet address of the machine the program is running on.

int sethostid (long int id)

Function

The **sethostid** function sets the address of the host machine to *id*. Only privileged processes are allowed to do this. Usually it happens just once, at system boot time.

The return value is 0 on success and -1 on failure. The following errno error condition is defined for this function:

EPERM This process cannot set the host name because it is not privileged.

26.2 Hardware/Software Type Identification

You can use the uname function to find out some information about the type of computer your program is running on. This function and the associated data type are declared in the header file 'sys/utsname.h'.

struct utsname Data Type

The utsname structure is used to hold information returned by the uname function. It has the following members:

char sysname[]

This is the name of the operating system in use.

char nodename[]

This is the network name of this particular computer. In the GNU library, the value is the same as that returned by gethostname; see Section 26.1 [Host Identification], page 541.

char release[]

This is the current release level of the operating system implementation.

char version[]

This is the current version level within the release of the operating system.

char machine∏

This is a description of the type of hardware that is in use.

The GNU C Library fills in this field based on the configuration name that was specified when building and installing the library. GNU uses a three-part name to describe a system configuration; the three parts are *cpu*, *manufacturer* and *system-type*, and they are separated with dashes. Any possible combination of three names is potentially meaningful, but most such combinations are meaningless in practice and even the meaningful ones are not necessarily supported by any particular GNU program.

Since the value in machine is supposed to describe just the hardware, it consists of the first two parts of the configuration name: 'cpu-manufacturer'.

Here is a list of all the possible alternatives:

```
"i386-anything", "m68k-hp", "sparc-sun", "m68k-sun", "m68k-sony", "mips-dec"
```

int uname (struct utsname *info)

Function

The uname function fills in the structure pointed to by *info* with information about the operating system and host machine. A non-negative value indicates that the data was successfully stored.

-1 as the value indicates an error. The only error possible is EFAULT, which we normally don't mention as it is always a possibility.

27 System Configuration Parameters

The functions and macros listed in this chapter give information about configuration parameters of the operating system—for example, capacity limits, presence of optional POSIX features, and the default path for executable files (see Section 27.12 [String Parameters], page 560).

27.1 General Capacity Limits

The POSIX.1 and POSIX.2 standards specify a number of parameters that describe capacity limitations of the system. These limits can be fixed constants for a given operating system, or they can vary from machine to machine. For example, some limit values may be configurable by the system administrator, either at run time or by rebuilding the kernel, and this should not require recompiling application programs.

Each of the following limit parameters has a macro that is defined in 'limits.h' only if the system has a fixed, uniform limit for the parameter in question. If the system allows different file systems or files to have different limits, then the macro is undefined; use sysconf to find out the limit that applies at a particular time on a particular machine. See Section 27.4 [Sysconf], page 549.

Each of these parameters also has another macro, with a name starting with '_POSIX', which gives the lowest value that the limit is allowed to have on any POSIX system. See Section 27.5 [Minimums], page 552.

int ARG_MAX Macro

If defined, the unvarying maximum combined length of the argv and environ arguments that can be passed to the exec functions.

int CHILD_MAX Macro

If defined, the unvarying maximum number of processes that can exist with the same real user ID at any one time.

int OPEN_MAX Macro

If defined, the unvarying maximum number of files that a single process can have open simultaneously.

int STREAM_MAX

Macro

If defined, the unvarying maximum number of streams that a single process can have open simultaneously. See Section 11.3 [Opening Streams], page 140.

int TZNAME_MAX

Macro

If defined, the unvarying maximum length of a time zone name. See Section 19.2.6 [Time Zone Functions], page 385.

These limit macros are always defined in 'limits.h'.

int NGROUPS_MAX

Macro

The maximum number of supplementary group IDs that one process can have.

The value of this macro is actually a lower bound for the maximum. That is, you can count on being able to have that many supplementary group IDs, but a particular machine might let you have even more. You can use sysconf to see whether a particular machine will let you have more (see Section 27.4 [Sysconf], page 549).

int SSIZE_MAX Macro

The largest value that can fit in an object of type ssize_t. Effectively, this is the limit on the number of bytes that can be read or written in a single operation.

This macro is defined in all POSIX systems because this limit is never configurable.

int RE_DUP_MAX Macro

The largest number of repetitions you are guaranteed is allowed in the construct $\{\min, \max\}$ in a regular expression.

The value of this macro is actually a lower bound for the maximum. That is, you can count on being able to have that many supplementary group IDs, but a particular machine might let you have even more. You can use sysconf to see whether a particular machine will let you have more (see Section 27.4 [Sysconf], page 549). And even the value that sysconf tells you is just a lower bound—larger values might work.

This macro is defined in all POSIX.2 systems, because POSIX.2 says it should always be defined even if there is no specific imposed limit.

27.2 Overall System Options

POSIX defines certain system-specific options that not all POSIX systems support. Since these options are provided in the kernel, not in the library, simply using the GNU C library does not guarantee any of these features is supported; it depends on the system you are using.

You can test for the availability of a given option using the macros in this section, together with the function sysconf. The macros are defined only if you include 'unistd.h'.

For the following macros, if the macro is defined in 'unistd.h', then the option is supported. Otherwise, the option may or may not be supported; use sysconf to find out. See Section 27.4 [Sysconf], page 549.

int _POSIX_JOB_CONTROL

Macro

If this symbol is defined, it indicates that the system supports job control. Otherwise, the implementation behaves as if all processes within a session belong to a single process group. See Chapter 24 [Job Control], page 495.

int _POSIX_SAVED_IDS

Macro

If this symbol is defined, it indicates that the system remembers the effective user and group IDs of a process before it executes an executable file with the set-user-ID or set-group-ID bits set, and that explicitly changing the effective user or group IDs back to these values is permitted. If this option is not defined, then if a nonprivileged process changes its effective user or group ID to the real user or group ID of the process, it can't change it back again. See Section 25.8 [Enable/Disable Setuid], page 527.

For the following macros, if the macro is defined in 'unistd.h', then its value indicates whether the option is supported. A value of -1 means no, and any other value means yes. If the macro is not defined, then the option may or may not be supported; use sysconf to find out. See Section 27.4 [Sysconf], page 549.

int POSIX2_C_DEV

Macro

If this symbol is defined, it indicates that the system has the POSIX.2 C compiler command, c89. The GNU C library always defines this as 1, on the assumption that you would not have installed it if you didn't have a C compiler.

int _POSIX2_FORT_DEV

Macro

If this symbol is defined, it indicates that the system has the POSIX.2 Fortran compiler command, fort77. The GNU C library never defines this, because we don't know what the system has.

int _POSIX2_FORT_RUN

Macro

If this symbol is defined, it indicates that the system has the POSIX.2 as a command to interpret Fortran carriage control. The GNU C library never defines this, because we don't know what the system has.

int _POSIX2_LOCALEDEF

Macro

If this symbol is defined, it indicates that the system has the POSIX.2 localedef command. The GNU C library never defines this, because we don't know what the system has.

int POSIX2-SW-DEV

Macro

If this symbol is defined, it indicates that the system has the POSIX.2 commands ar, make, and strip. The GNU C library always defines this as 1, on the assumption that you had to have ar and make to install the library, and it's unlikely that strip would be absent when those are present.

27.3 Which Version of POSIX is Supported

long int _POSIX_VERSION

Macro

This constant represents the version of the POSIX.1 standard to which the implementation conforms. For an implementation conforming to the 1990 POSIX.1 standard, the value is the integer 199009L.

_POSIX_VERSION is always defined (in 'unistd.h') in any POSIX system.

Usage Note: Don't try to test whether the system supports POSIX by including 'unistd.h' and then checking whether _POSIX_VERSION is defined. On a non-POSIX system, this will probably fail because there is no 'unistd.h'. We do not know of any way you can reliably test at compilation time whether your target system supports POSIX or whether 'unistd.h' exists.

The GNU C compiler predefines the symbol __POSIX__ if the target system is a POSIX system. Provided you do not use any other compilers on POSIX systems, testing defined (__POSIX__) will reliably detect such systems.

long int _POSIX2_C_VERSION

Macro

This constant represents the version of the POSIX.2 standard which the library and system kernel support. We don't know what value this will be for the first version of the POSIX.2 standard, because the value is based on the year and month in which the standard is officially adopted.

The value of this symbol says nothing about the utilities installed on the system.

Usage Note: You can use this macro to tell whether a POSIX.1 system library supports POSIX.2 as well. Any POSIX.1 system contains 'unistd.h', so include that file and then test defined (_POSIX2_C_VERSION).

27.4 Using sysconf

When your system has configurable system limits, you can use the **sysconf** function to find out the value that applies to any particular machine. The function and the associated *parameter* constants are declared in the header file 'unistd.h'.

27.4.1 Definition of sysconf

long int sysconf (int parameter)

Function

This function is used to inquire about runtime system parameters. The parameter argument should be one of the '_SC_' symbols listed below.

The normal return value from sysconf is the value you requested. A value of -1 is returned both if the implementation does not impose a limit, and in case of an error.

The following errno error conditions are defined for this function:

EINVAL The value of the parameter is invalid.

27.4.2 Constants for sysconf Parameters

Here are the symbolic constants for use as the *parameter* argument to **sysconf**. The values are all integer constants (more specifically, enumeration type values).

_SC_ARG_MAX

Inquire about the parameter corresponding to ARG_MAX.

_SC_CHILD_MAX

Inquire about the parameter corresponding to CHILD_MAX.

_SC_OPEN_MAX

Inquire about the parameter corresponding to OPEN_MAX.

_SC_STREAM_MAX

Inquire about the parameter corresponding to STREAM_MAX.

_SC_TZNAME_MAX

Inquire about the parameter corresponding to TZNAME_MAX.

_SC_NGROUPS_MAX

Inquire about the parameter corresponding to NGROUPS_MAX.

_SC_JOB_CONTROL

Inquire about the parameter corresponding to _POSIX_JOB_CONTROL.

_SC_SAVED_IDS

Inquire about the parameter corresponding to _POSIX_SAVED_IDS.

_SC_VERSION

Inquire about the parameter corresponding to _POSIX_VERSION.

_SC_CLK_TCK

Inquire about the parameter corresponding to CLOCKS_PER_SEC; see Section 19.1.1 [Basic CPU Time], page 371.

_SC_2_C_DEV

Inquire about whether the system has the POSIX.2 C compiler command, c89.

_SC_2_FORT_DEV

Inquire about whether the system has the POSIX.2 Fortran compiler command, fort77.

_SC_2_FORT_RUN

Inquire about whether the system has the POSIX.2 as a command to interpret Fortran carriage control.

_SC_2_LOCALEDEF

Inquire about whether the system has the POSIX.2 localedef command.

_SC_2_SW_DEV

Inquire about whether the system has the POSIX.2 commands ar, make, and strip.

_SC_BC_BASE_MAX

Inquire about the maximum value of obase in the bc utility.

_SC_BC_DIM_MAX

Inquire about the maximum size of an array in the bc utility.

_SC_BC_SCALE_MAX

Inquire about the maximum value of scale in the bc utility.

_SC_BC_STRING_MAX

Inquire about the maximum size of a string constant in the bc utility.

_SC_COLL_WEIGHTS_MAX

Inquire about the maximum number of weights that can necessarily be used in defining the collating sequence for a locale.

_SC_EXPR_NEST_MAX

Inquire about the maximum number of expressions nested within parentheses when using the expr utility.

_SC_LINE_MAX

Inquire about the maximum size of a text line that the POSIX.2 text utilities can handle.

_SC_VERSION

Inquire about the version number of POSIX.1 that the library and kernel support.

_SC_2_VERSION

Inquire about the version number of POSIX.2 that the system utilities support.

27.4.3 Examples of sysconf

We recommend that you first test for a macro definition for the parameter you are interested in, and call **sysconf** only if the macro is not defined. For example, here is how to test whether job control is supported:

```
int
have_job_control (void)
{
#ifdef _POSIX_JOB_CONTROL
   return 1;
#else
   int value = sysconf (_SC_JOB_CONTROL);
   if (value < 0)
      /* If the system is that badly wedged,
            there's no use trying to go on. */
      fatal (strerror (errno));
   return value;
#endif
}</pre>
```

Here is how to get the value of a numeric limit:

```
int
get_child_max ()
{
#ifdef CHILD_MAX
   return CHILD_MAX;
#else
   int value = sysconf (_SC_CHILD_MAX);
   if (value < 0)
     fatal (strerror (errno));
   return value;
#endif
}</pre>
```

27.5 Minimum Values for General Capacity Limits

Here are the names for the POSIX minimum upper bounds for the system limit parameters. The significance of these values is that you can safely push to these limits without checking whether the particular system you are using can go that far.

_POSIX_ARG_MAX

The value of this macro is the most restrictive limit permitted by POSIX for the maximum combined length of the argv and environ arguments that can be passed to the exec functions. Its value is 4096.

_POSIX_CHILD_MAX

The value of this macro is the most restrictive limit permitted by POSIX for the maximum number of simultaneous processes per real user ID. Its value is 6.

_POSIX_NGROUPS_MAX

The value of this macro is the most restrictive limit permitted by POSIX for the maximum number of supplementary group IDs per process. Its value is 0.

_POSIX_OPEN_MAX

The value of this macro is the most restrictive limit permitted by POSIX for the maximum number of files that a single process can have open simultaneously. Its value is 16.

_POSIX_SSIZE_MAX

The value of this macro is the most restrictive limit permitted by POSIX for the maximum value that can be stored in an object of type ssize_t. Its value is 32767.

POSIX STREAM MAX

The value of this macro is the most restrictive limit permitted by POSIX for the maximum number of streams that a single process can have open simultaneously. Its value is 8.

_POSIX_TZNAME_MAX

The value of this macro is the most restrictive limit permitted by POSIX for the maximum length of a time zone name. Its value is 3.

_POSIX2_RE_DUP_MAX

The value of this macro is the most restrictive limit permitted by POSIX for the numbers used in the ' $\{min, max\}$ ' construct in a regular expression. Its value is 255.

27.6 Limits on File System Capacity

The POSIX.1 standard specifies a number of parameters that describe the limitations of the file system. It's possible for the system to have a fixed, uniform limit for a parameter, but this isn't the usual case. On most systems, it's possible for different file systems (and, for some parameters, even different files) to have different maximum limits. For example, this is very likely if you use NFS to mount some of the file systems from other machines.

Each of the following macros is defined in 'limits.h' only if the system has a fixed, uniform limit for the parameter in question. If the system allows different file systems or files to have different limits, then the macro is undefined; use pathconf or fpathconf to find out the limit that applies to a particular file. See Section 27.9 [Pathconf], page 557.

554

Each parameter also has another macro, with a name starting with '_POSIX', which gives the lowest value that the limit is allowed to have on any POSIX system. See Section 27.8 [File Minimums], page 556.

int LINK_MAX Macro

The uniform system limit (if any) for the number of names for a given file. See Section 13.3 [Hard Links], page 239.

int MAX_CANON Macro

The uniform system limit (if any) for the amount of text in a line of input when input editing is enabled. See Section 16.3 [Canonical or Not], page 322.

int MAX_INPUT Macro

The uniform system limit (if any) for the total number of characters typed ahead as input. See Section 16.2 [I/O Queues], page 322.

int NAME_MAX Macro

The uniform system limit (if any) for the length of a file name component.

int PATH_MAX Macro

The uniform system limit (if any) for the length of an entire file name (that is, the argument given to system calls such as open).

int PIPE_BUF Macro

The uniform system limit (if any) for the number of bytes that can be written atomically to a pipe. If multiple processes are writing to the same pipe simultaneously, output from different processes might be interleaved in chunks of this size. See Chapter 14 [Pipes and FIFOs], page 263.

These are alternative macro names for some of the same information.

int MAXNAMLEN

Macro

This is the BSD name for NAME_MAX. It is defined in 'dirent.h'.

int FILENAME_MAX

Macro

The value of this macro is an integer constant expression that represents the maximum length of a file name string. It is defined in 'stdio.h'.

Unlike PATH_MAX, this macro is defined even if there is no actual limit imposed. In such a case, its value is typically a very large number. This is always the case on the GNU system.

Usage Note: Don't use FILENAME_MAX as the size of an array in which to store a file name! You can't possibly make an array that big! Use dynamic allocation (see Chapter 3 [Memory Allocation], page 29) instead.

27.7 Optional Features in File Support

POSIX defines certain system-specific options in the system calls for operating on files. Some systems support these options and others do not. Since these options are provided in the kernel, not in the library, simply using the GNU C library does not guarantee any of these features is supported; it depends on the system you are using. They can also vary between file systems on a single machine.

This section describes the macros you can test to determine whether a particular option is supported on your machine. If a given macro is defined in 'unistd.h', then its value says whether the corresponding feature is supported. (A value of -1 indicates no; any other value indicates yes.) If the macro is undefined, it means particular files may or may not support the feature.

Since all the machines that support the GNU C library also support NFS, one can never make a general statement about whether all file systems support the <code>_POSIX_CHOWN_RESTRICTED</code> and <code>_POSIX_NO_TRUNC</code> features. So these names are never defined as macros in the GNU C library.

int _POSIX_CHOWN_RESTRICTED

Macro

If this option is in effect, the **chown** function is restricted so that the only changes permitted to nonprivileged processes is to change the group owner of a file to either be the effective group ID of the process, or one of its supplementary group IDs. See Section 13.8.4 [File Owner], page 252.

int _POSIX_NO_TRUNC

Macro

If this option is in effect, file name components longer than NAME_MAX generate an ENAMETOOLONG error. Otherwise, file name components that are too long are silently truncated.

unsigned char _POSIX_VDISABLE

Macro

This option is only meaningful for files that are terminal devices. If it is enabled, then handling for special control characters can be disabled individually. See Section 16.4.9 [Special Characters], page 335.

If one of these macros is undefined, that means that the option might be in effect for some files and not for others. To inquire about a particular file, call pathconf or fpathconf. See Section 27.9 [Pathconf], page 557.

27.8 Minimum Values for File System Limits

Here are the names for the POSIX minimum upper bounds for some of the above parameters. The significance of these values is that you can safely push to these limits without checking whether the particular system you are using can go that far.

_POSIX_LINK_MAX

The most restrictive limit permitted by POSIX for the maximum value of a file's link count. The value of this constant is 8; thus, you can always make up to eight names for a file without running into a system limit.

_POSIX_MAX_CANON

The most restrictive limit permitted by POSIX for the maximum number of bytes in a canonical input line from a terminal device. The value of this constant is 255.

_POSIX_MAX_INPUT

The most restrictive limit permitted by POSIX for the maximum number of bytes in a terminal device input queue (or typeahead buffer). See Section 16.4.4 [Input Modes], page 327. The value of this constant is 255.

_POSIX_NAME_MAX

The most restrictive limit permitted by POSIX for the maximum number of bytes in a file name component. The value of this constant is 14.

_POSIX_PATH_MAX

The most restrictive limit permitted by POSIX for the maximum number of bytes in a file name. The value of this constant is 255.

_POSIX_PIPE_BUF

The most restrictive limit permitted by POSIX for the maximum number of bytes that can be written atomically to a pipe. The value of this constant is 512.

27.9 Using pathconf

When your machine allows different files to have different values for a file system parameter, you can use the functions in this section to find out the value that applies to any particular file.

These functions and the associated constants for the *parameter* argument are declared in the header file 'unistd.h'.

long int pathconf (const char *filename, int parameter)

Function

This function is used to inquire about the limits that apply to the file named filename.

The parameter argument should be one of the '_PC_' constants listed below.

The normal return value from pathconf is the value you requested. A value of -1 is returned both if the implementation does not impose a limit, and in case of an error. In the former case, errno is not set, while in the latter case, errno is set to indicate the cause of the problem. So the only way to use this function robustly is to store 0 into errno just before calling it.

Besides the usual file name syntax errors (see Section 10.2.3 [File Name Errors], page 136), the following error condition is defined for this function:

The value of *parameter* is invalid, or the implementation doesn't support the *parameter* for the specific file.

long int fpathconf (int filedes, int parameter)

Function

This is just like **pathconf** except that an open file descriptor is used to specify the file for which information is requested, instead of a file name.

The following errno error conditions are defined for this function:

EBADF The filedes argument is not a valid file descriptor.

558 The GNU C Library

The value of *parameter* is invalid, or the implementation doesn't support the *parameter* for the specific file.

Here are the symbolic constants that you can use as the *parameter* argument to pathconf and fpathconf. The values are all integer constants.

_PC_LINK_MAX

Inquire about the parameter corresponding to LINK_MAX.

_PC_MAX_CANON

Inquire about the parameter corresponding to MAX_CANON.

_PC_MAX_INPUT

Inquire about the parameter corresponding to MAX_INPUT.

_PC_NAME_MAX

Inquire about the parameter corresponding to NAME_MAX.

_PC_PATH_MAX

Inquire about the parameter corresponding to PATH_MAX.

_PC_PIPE_BUF

Inquire about the parameter corresponding to PIPE_BUF.

_PC_CHOWN_RESTRICTED

Inquire about the parameter corresponding to _POSIX_CHOWN_RESTRICTED.

_PC_NO_TRUNC

Inquire about the parameter corresponding to _POSIX_NO_TRUNC.

_PC_VDISABLE

Inquire about the parameter corresponding to _POSIX_VDISABLE.

27.10 Utility Program Capacity Limits

The POSIX.2 standard specifies certain system limits that you can access through sysconf that apply to utility behavior rather than the behavior of the library or the operating system.

The GNU C library defines macros for these limits, and sysconf returns values for them if you ask; but these values convey no meaningful information. They are simply the smallest values that POSIX.2 permits.

int BC_BASE_MAX

Macro

The largest value of obase that the bc utility is guaranteed to support.

int BC_SCALE_MAX

Macro

The largest value of scale that the bc utility is guaranteed to support.

int BC_DIM_MAX

Macro

The largest number of elements in one array that the bc utility is guaranteed to support.

int BC_STRING_MAX

Macro

The largest number of characters in one string constant that the **bc** utility is guaranteed to support.

int BC_DIM_MAX

Macro

The largest number of elements in one array that the bc utility is guaranteed to support.

int COLL_WEIGHTS_MAX

Macro

The largest number of weights that can necessarily be used in defining the collating sequence for a locale.

int EXPR_NEST_MAX

Macro

The maximum number of expressions that can be nested within parenthesis by the expr utility.

int LINE_MAX

Macro

The largest text line that the text-oriented POSIX.2 utilities can support. (If you are using the GNU versions of these utilities, then there is no actual limit except that imposed by the available virtual memory, but there is no way that the library can tell you this.)

27.11 Minimum Values for Utility Limits

_POSIX2_BC_BASE_MAX

The most restrictive limit permitted by POSIX.2 for the maximum value of obase in the bc utility. Its value is 99.

560 The GNU C Library

_POSIX2_BC_DIM_MAX

The most restrictive limit permitted by POSIX.2 for the maximum size of an array in the bc utility. Its value is 2048.

_POSIX2_BC_SCALE_MAX

The most restrictive limit permitted by POSIX.2 for the maximum value of scale in the bc utility. Its value is 99.

_POSIX2_BC_STRING_MAX

The most restrictive limit permitted by POSIX.2 for the maximum size of a string constant in the bc utility. Its value is 1000.

_POSIX2_COLL_WEIGHTS_MAX

The most restrictive limit permitted by POSIX.2 for the maximum number of weights that can necessarily be used in defining the collating sequence for a locale. Its value is 2.

_POSIX2_EXPR_NEST_MAX

The most restrictive limit permitted by POSIX.2 for the maximum number of expressions nested within parenthesis when using the expr utility. Its value is 32.

_POSIX2_LINE_MAX

The most restrictive limit permitted by POSIX.2 for the maximum size of a text line that the text utilities can handle. Its value is 2048.

27.12 String-Valued Parameters

POSIX.2 defines a way to get string-valued parameters from the operating system with the function confstr:

size_t confstr (int parameter, char *buf, size_t len)

Function

This function reads the value of a string-valued system parameter, storing the string into len bytes of memory space starting at buf. The parameter argument should be one of the '_CS_' symbols listed below.

The normal return value from confstr is the length of the string value that you asked for. If you supply a null pointer for *buf*, then confstr does not try to store the string; it just returns its length. A value of 0 indicates an error.

If the string you asked for is too long for the buffer (that is, longer than len - 1), then confstr stores just that much (leaving room for the terminating null character). You

can tell that this has happened because **confstr** returns a value greater than or equal to *len*.

The following errno error conditions are defined for this function:

EINVAL The value of the parameter is invalid.

Currently there is just one parameter you can read with confstr:

_CS_PATH This parameter's value is the recommended default path for searching for executable files. This is the path that a user has by default just after logging in.

The way to use confstr without any arbitrary limit on string size is to call it twice: first call it to get the length, allocate the buffer accordingly, and then call confstr again to fill the buffer, like this:

```
char *
get_default_path (void)
{
    size_t len = confstr (_CS_PATH, NULL, 0);
    char *buffer = (char *) xmalloc (len);
    if (confstr (_CS_PATH, buf, len + 1) == 0)
      {
        free (buffer);
        return NULL;
    }
    return buffer;
}
```

562

Appendix A C Language Facilities Implemented By the Library

Some of the facilities implemented by the C library really should be thought of as parts of the C language itself. These facilities ought to be documented in the C Language Manual, not in the library manual; but since we don't have the language manual yet, and documentation for these features has been written, we are publishing it here.

A.1 Explicitly Checking Internal Consistency

When you're writing a program, it's often a good idea to put in checks at strategic places for "impossible" errors or violations of basic assumptions. These checks are helpful in debugging problems due to misunderstandings between different parts of the program.

The assert macro, defined in the header file 'assert.h', provides a convenient way to abort the program while printing a message about where in the program the error was detected.

Once you think your program is debugged, you can disable the error checks performed by the assert macro by recompiling with the macro NDEBUG defined. This means you don't actually have to change the program source code to disable these checks.

But disabling these consistency checks is undesirable unless they make the program significantly slower. All else being equal, more error checking is good no matter who is running the program. A wise user would rather have a program crash, visibly, than have it return nonsense without indicating anything might be wrong.

void assert (int expression)

Macro

Verify the programmer's belief that expression should be nonzero at this point in the program.

If NDEBUG is not defined, assert tests the value of expression. If it is false (zero), assert aborts the program (see Section 22.3.4 [Aborting a Program], page 479) after printing a message of the form:

'file': linenum: Assertion 'expression' failed.

on the standard error stream stderr (see Section 11.2 [Standard Streams], page 139). The filename and line number are taken from the C preprocessor macros __FILE__ and __LINE__ and specify where the call to assert was written.

If the preprocessor macro NDEBUG is defined at the point where 'assert.h' is included, the assert macro is defined to do absolutely nothing.

Warning: Even the argument expression expression is not evaluated if NDEBUG is in effect. So never use assert with arguments that involve side effects. For example, assert (++i > 0); is a bad idea, because i will not be incremented if NDEBUG is defined.

Usage note: The assert facility is designed for detecting internal inconsistency; it is not suitable for reporting invalid input or improper usage by the user of the program.

The information in the diagnostic messages printed by the assert macro is intended to help you, the programmer, track down the cause of a bug, but is not really useful for telling a user of your program why his or her input was invalid or why a command could not be carried out. So you can't use assert to print the error messages for these eventualities.

What's more, your program should not abort when given invalid input, as assert would do—it should exit with nonzero status (see Section 22.3.2 [Exit Status], page 476) after printing its error messages, or perhaps read another command or move on to the next input file.

See Section 2.3 [Error Messages], page 25, for information on printing error messages for problems that do not represent bugs in the program.

A.2 Variadic Functions

ANSI C defines a syntax for declaring a function to take a variable number or type of arguments. (Such functions are referred to as varargs functions or variadic functions.) However, the language itself provides no mechanism for such functions to access their non-required arguments; instead, you use the variable arguments macros defined in 'stdarg.h'.

This section describes how to declare variadic functions, how to write them, and how to call them properly.

Compatibility Note: Many older C dialects provide a similar, but incompatible, mechanism for defining functions with variable numbers of arguments, using 'varargs.h'.

A.2.1 Why Variadic Functions are Used

Ordinary C functions take a fixed number of arguments. When you define a function, you specify the data type for each argument. Every call to the function should supply the expected number of arguments, with types that can be converted to the specified ones. Thus, if the function 'foo' is declared with int foo (int, char *); then you must call it with two arguments, a number (any kind will do) and a string pointer.

But some functions perform operations that can meaningfully accept an unlimited number of arguments.

In some cases a function can handle any number of values by operating on all of them as a block. For example, consider a function that allocates a one-dimensional array with malloc to hold a specified set of values. This operation makes sense for any number of values, as long as the length of the array corresponds to that number. Without facilities for variable arguments, you would have to define a separate function for each possible array size.

The library function **printf** (see Section 11.9 [Formatted Output], page 150) is an example of another class of function where variable arguments are useful. This function prints its arguments (which can vary in type as well as number) under the control of a format template string.

These are good reasons to define a *variadic* function which can handle as many arguments as the caller chooses to pass.

Some functions such as open take a fixed set of arguments, but occasionally ignore the last few. Strict adherence to ANSI C requires these functions to be defined as variadic; in practice, however, the GNU C compiler and most other C compilers let you define such a function to take a fixed set of arguments—the most it can ever use—and then only declare the function as variadic (or not declare its arguments at all!).

A.2.2 How Variadic Functions are Defined and Used

Defining and using a variadic function involves three steps:

- Define the function as variadic, using an ellipsis ('...') in the argument list, and using special macros to access the variable arguments. See Section A.2.2.2 [Receiving Arguments], page 566.
- Declare the function as variadic, using a prototype with an ellipsis ('...'), in all the files which call it. See Section A.2.2.1 [Variadic Prototypes], page 566.
- Call the function by writing the fixed arguments followed by the additional variable arguments. See Section A.2.2.4 [Calling Variadics], page 568.

A.2.2.1 Syntax for Variable Arguments

A function that accepts a variable number of arguments must be declared with a prototype that says so. You write the fixed arguments as usual, and then tack on '...' to indicate the possibility of additional arguments. The syntax of ANSI C requires at least one fixed argument before the '...'. For example,

```
int
func (const char *a, int b, ...)
{
    ...
}
```

outlines a definition of a function func which returns an int and takes two required arguments, a const char * and an int. These are followed by any number of anonymous arguments.

Portability note: For some C compilers, the last required argument must not be declared register in the function definition. Furthermore, this argument's type must be self-promoting: that is, the default promotions must not change its type. This rules out array and function types, as well as float, char (whether signed or not) and short int (whether signed or not). This is actually an ANSI C requirement.

A.2.2.2 Receiving the Argument Values

Ordinary fixed arguments have individual names, and you can use these names to access their values. But optional arguments have no names—nothing but '...'. How can you access them?

The only way to access them is sequentially, in the order they were written, and you must use special macros from 'stdarg.h' in the following three step process:

- 1. You initialize an argument pointer variable of type va_list using va_start. The argument pointer when initialized points to the first optional argument.
- 2. You access the optional arguments by successive calls to va_arg. The first call to va_arg gives you the first optional argument, the next call gives you the second, and so on.
 - You can stop at any time if you wish to ignore any remaining optional arguments. It is perfectly all right for a function to access fewer arguments than were supplied in the call, but you will get garbage values if you try to access too many arguments.
- 3. You indicate that you are finished with the argument pointer variable by calling va_end.

 (In practice, with most C compilers, calling va_end does nothing and you do not really need to call it. This is always true in the GNU C compiler. But you might as well call va_end just in case your program is someday compiled with a peculiar compiler.)

See Section A.2.2.5 [Argument Macros], page 569, for the full definitions of va_start, va_arg and va_end.

Steps 1 and 3 must be performed in the function that accepts the optional arguments. However, you can pass the va_list variable as an argument to another function and perform all or part of step 2 there.

You can perform the entire sequence of the three steps multiple times within a single function invocation. If you want to ignore the optional arguments, you can do these steps zero times.

You can have more than one argument pointer variable if you like. You can initialize each variable with va_start when you wish, and then you can fetch arguments with each argument pointer as you wish. Each argument pointer variable will sequence through the same set of argument values, but at its own pace.

Portability note: With some compilers, once you pass an argument pointer value to a subroutine, you must not keep using the same argument pointer value after that subroutine returns. For full portability, you should just pass it to va_end. This is actually an ANSI C requirement, but most ANSI C compilers work happily regardless.

A.2.2.3 How Many Arguments Were Supplied

There is no general way for a function to determine the number and type of the optional arguments it was called with. So whoever designs the function typically designs a convention for

568 The GNU C Library

the caller to tell it how many arguments it has, and what kind. It is up to you to define an appropriate calling convention for each variadic function, and write all calls accordingly.

One kind of calling convention is to pass the number of optional arguments as one of the fixed arguments. This convention works provided all of the optional arguments are of the same type.

A similar alternative is to have one of the required arguments be a bit mask, with a bit for each possible purpose for which an optional argument might be supplied. You would test the bits in a predefined sequence; if the bit is set, fetch the value of the next argument, otherwise use a default value.

A required argument can be used as a pattern to specify both the number and types of the optional arguments. The format string argument to printf is one example of this (see Section 11.9.7 [Formatted Output Functions], page 159).

Another possibility is to pass an "end marker" value as the last optional argument. For example, for a function that manipulates an arbitrary number of pointer arguments, a null pointer might indicate the end of the argument list. (This assumes that a null pointer isn't otherwise meaningful to the function.) The execl function works in just this way; see Section 23.5 [Executing a File], page 485.

A.2.2.4 Calling Variadic Functions

You don't have to write anything special when you call a variadic function. Just write the arguments (required arguments, followed by optional ones) inside parentheses, separated by commas, as usual. But you should prepare by declaring the function with a prototype, and you must know how the argument values are converted.

In principle, functions that are defined to be variadic must also be declared to be variadic using a function prototype whenever you call them. (See Section A.2.2.1 [Variadic Prototypes], page 566, for how.) This is because some C compilers use a different calling convention to pass the same set of argument values to a function depending on whether that function takes variable arguments or fixed arguments.

In practice, the GNU C compiler always passes a given set of argument types in the same way regardless of whether they are optional or required. So, as long as the argument types are self-promoting, you can safely omit declaring them. Usually it is a good idea to declare the argument

types for variadic functions, and indeed for all functions. But there are a few functions which it is extremely convenient not to have to declare as variadic—for example, open and printf.

Since the prototype doesn't specify types for optional arguments, in a call to a variadic function the default argument promotions are performed on the optional argument values. This means the objects of type char or short int (whether signed or not) are promoted to either int or unsigned int, as appropriate; and that objects of type float are promoted to type double. So, if the caller passes a char as an optional argument, it is promoted to an int, and the function should get it with va_arg (ap, int).

Conversion of the required arguments is controlled by the function prototype in the usual way: the argument expression is converted to the declared argument type as if it were being assigned to a variable of that type.

A.2.2.5 Argument Access Macros

Here are descriptions of the macros used to retrieve variable arguments. These macros are defined in the header file 'stdarg.h'.

va_list Data Type

The type va_list is used for argument pointer variables.

void va_start (va_list ap, last required)

Macro

This macro initializes the argument pointer variable ap to point to the first of the optional arguments of the current function; last_required must be the last required argument to the function.

See Section A.2.3.1 [Old Varargs], page 571, for an alternate definition of va_start found in the header file 'varargs.h'.

type va_arg (va_list ap, type)

Macro

The va_arg macro returns the value of the next optional argument, and modifies the value of ap to point to the subsequent argument. Thus, successive uses of va_arg return successive optional arguments.

The type of the value returned by va_arg is type as specified in the call. type must be a self-promoting type (not char or short int or float) that matches the type of the actual argument.

```
void va_end (va_list ap)
```

Macro

This ends the use of ap. After a va_end call, further va_arg calls with the same ap may not work. You should invoke va_end before returning from the function in which va_start was invoked with the same ap argument.

In the GNU C library, va_end does nothing, and you need not ever use it except for reasons of portability.

A.2.3 Example of a Variadic Function

Here is a complete sample function that accepts a variable number of arguments. The first argument to the function is the count of remaining arguments, which are added up and the result returned. While trivial, this function is sufficient to illustrate how to use the variable arguments facility.

```
#include <stdarg.h>
#include <stdio.h>
add_em_up (int count,...)
  va_list ap;
  int i, sum;
  va_start (ap, count); /* Initialize the argument list. */
  sum = 0;
  for (i = 0; i < count; i++)
    sum += va_arg (ap, int); /* Get the next argument value. */
  va_end (ap); /* Clean up. */
  return sum;
}
int
main (void)
  /* This call prints 16. */
  printf ("d\n", add_em_up (3, 5, 5, 6));
```

```
/* This call prints 55. */
printf ("%d\n", add_em_up (10, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10));
return 0;
}
```

A.2.3.1 Old-Style Variadic Functions

Before ANSI C, programmers used a slightly different facility for writing variadic functions. The GNU C compiler still supports it; currently, it is more portable than the ANSI C facility, since support for ANSI C is still not universal. The header file which defines the old-fashioned variadic facility is called 'varargs.h'.

Using 'varargs.h' is almost the same as using 'stdarg.h'. There is no difference in how you call a variadic function; See Section A.2.2.4 [Calling Variadics], page 568. The only difference is in how you define them. First of all, you must use old-style non-prototype syntax, like this:

```
tree
build (va_alist)
      va_dcl
{
```

Secondly, you must give va_start just one argument, like this:

```
va_list p;
va_start (p);
```

These are the special macros used for defining old-style variadic functions:

va_alist Macro

This macro stands for the argument name list required in a variadic function.

va_dcl Macro

This macro declares the implicit argument or arguments for a variadic function.

The GNU C Library

void va_start (va_list ap)

Macro

This macro, as defined in 'varargs.h', initializes the argument pointer variable ap to point to the first argument of the current function.

The other argument macros, va_arg and va_end, are the same in 'varargs.h' as in 'stdarg.h'; see Section A.2.2.5 [Argument Macros], page 569 for details.

It does not work to include both 'varargs.h' and 'stdarg.h' in the same compilation; they define va_start in conflicting ways.

A.3 Null Pointer Constant

The null pointer constant is guaranteed not to point to any real object. You can assign it to any pointer variable since it has type void *. The preferred way to write a null pointer constant is with NULL.

void * NULL Macro

This is a null pointer constant.

You can also use 0 or (void *)0 as a null pointer constant, but using NULL is cleaner because it makes the purpose of the constant more evident.

If you use the null pointer constant as a function argument, then for complete portability you should make sure that the function has a prototype declaration. Otherwise, if the target machine has two different pointer representations, the compiler won't know which representation to use for that argument. You can avoid the problem by explicitly casting the constant to the proper pointer type, but we recommend instead adding a prototype for the function you are calling.

A.4 Important Data Types

The result of subtracting two pointers in C is always an integer, but the precise data type varies from C compiler to C compiler. Likewise, the data type of the result of sizeof also varies between compilers. ANSI defines standard aliases for these two types, so you can refer to them in a portable fashion. They are defined in the header file 'stddef.h'.

ptrdiff_t Data Type

This is the signed integer type of the result of subtracting two pointers. For example, with the declaration char *p1, *p2;, the expression p2 - p1 is of type ptrdiff_t. This will probably be one of the standard signed integer types (short int, int or long int), but might be a nonstandard type that exists only for this purpose.

size_t Data Type

This is an unsigned integer type used to represent the sizes of objects. The result of the sizeof operator is of this type, and functions such as malloc (see Section 3.3 [Unconstrained Allocation], page 30) and memcpy (see Section 5.4 [Copying and Concatenation], page 67) accept arguments of this type to specify object sizes.

Usage Note: size_t is the preferred way to declare any arguments or variables that hold the size of an object.

In the GNU system size_t is equivalent to either unsigned int or unsigned long int. These types have identical properties on the GNU system, and for most purposes, you can use them interchangeably. However, they are distinct as data types, which makes a difference in certain contexts.

For example, when you specify the type of a function argument in a function prototype, it makes a difference which one you use. If the system header files declare malloc with an argument of type size_t and you declare malloc with an argument of type unsigned int, you will get a compilation error if size_t happens to be unsigned long int on your system. To avoid any possibility of error, when a function argument or value is supposed to have type size_t, never declare its type in any other way.

Compatibility Note: Pre-ANSI C implementations generally used unsigned int for representing object sizes and int for pointer subtraction results. They did not necessarily define either size_t or ptrdiff_t. Unix systems did define size_t, in 'sys/types.h', but the definition was usually a signed type.

A.5 Data Type Measurements

Most of the time, if you choose the proper C data type for each object in your program, you need not be concerned with just how it is represented or how many bits it uses. When you do

need such information, the C language itself does not provide a way to get it. The header files

'limits.h' and 'float.h' contain macros which give you this information in full detail.

A.5.1 Computing the Width of an Integer Data Type

The most common reason that a program needs to know how many bits are in an integer type is for using an array of long int as a bit vector. You can access the bit at index n with

```
vector [n / LONGBITS] & (1 << (n % LONGBITS))
```

provided you define LONGBITS as the number of bits in a long int.

There is no operator in the C language that can give you the number of bits in an integer data type. But you can compute it from the macro CHAR_BIT, defined in the header file 'limits.h'.

CHAR_BIT This is the number of bits in a char—eight, on most systems. The value has type int.

You can compute the number of bits in any data type type like this:

$$sizeof (type) * CHAR_BIT$$

A.5.2 Range of an Integer Type

574

Suppose you need to store an integer value which can range from zero to one million. Which is the smallest type you can use? There is no general rule; it depends on the C compiler and target machine. You can use the 'MIN' and 'MAX' macros in 'limits.h' to determine which type will work.

Each signed integer type has a pair of macros which give the smallest and largest values that it can hold. Each unsigned integer type has one such macro, for the maximum value; the minimum value is, of course, zero.

The values of these macros are all integer constant expressions. The 'MAX' and 'MIN' macros for char and short int types have values of type int. The 'MAX' and 'MIN' macros for the other types have values of the same type described by the macro—thus, ULONG_MAX has type unsigned long int.

SCHAR_MIN

This is the minimum value that can be represented by a signed char.

SCHAR_MAX

UCHAR_MAX

These are the maximum values that can be represented by a signed char and unsigned char, respectively.

CHAR_MIN

This is the minimum value that can be represented by a char. It's equal to SCHAR_MIN if char is signed, or zero otherwise.

CHAR_MAX

This is the maximum value that can be represented by a char. It's equal to SCHAR_MAX if char is signed, or UCHAR_MAX otherwise.

SHRT_MIN

This is the minimum value that can be represented by a signed short int. On most machines that the GNU C library runs on, short integers are 16-bit quantities.

SHRT_MAX

USHRT_MAX

These are the maximum values that can be represented by a signed short int and unsigned short int, respectively.

INT_MIN

This is the minimum value that can be represented by a signed int. On most machines that the GNU C system runs on, an int is a 32-bit quantity.

INT_MAX

UINT_MAX

These are the maximum values that can be represented by, respectively, the type signed int and the type unsigned int.

LONG_MIN

This is the minimum value that can be represented by a signed long int. On most machines that the GNU C system runs on, long integers are 32-bit quantities, the same size as int.

LONG_MAX

ULONG_MAX

These are the maximum values that can be represented by a signed long int and unsigned long int, respectively.

LONG_LONG_MIN

This is the minimum value that can be represented by a signed long long int. On most machines that the GNU C system runs on, long long integers are 64-bit quantities.

LONG_LONG_MAX
ULONG_LONG_MAX

These are the maximum values that can be represented by a signed long long int and unsigned long long int, respectively.

WCHAR_MAX

This is the maximum value that can be represented by a wchar_t. See (undefined) [Wide Character Intro], page (undefined).

The header file 'limits.h' also defines some additional constants that parameterize various operating system and file system limits. These constants are described in Chapter 27 [System Configuration], page 545.

A.5.3 Floating Type Macros

The specific representation of floating point numbers varies from machine to machine. Because floating point numbers are represented internally as approximate quantities, algorithms for manipulating floating point data often need to take account of the precise details of the machine's floating point representation.

Some of the functions in the C library itself need this information; for example, the algorithms for printing and reading floating point numbers (see Chapter 11 [I/O on Streams], page 139) and for calculating trigonometric and irrational functions (see Chapter 17 [Mathematics], page 349) use it to avoid round-off error and loss of accuracy. User programs that implement numerical analysis techniques also often need this information in order to minimize or compute error bounds.

The header file 'float.h' describes the format used by your machine.

A.5.3.1 Floating Point Representation Concepts

This section introduces the terminology for describing floating point representations.

You are probably already familiar with most of these concepts in terms of scientific or exponential notation for floating point numbers. For example, the number 123456.0 could be expressed in exponential notation as 1.23456e+05, a shorthand notation indicating that the mantissa 1.23456 is multiplied by the base 10 raised to power 5.

More formally, the internal representation of a floating point number can be characterized in terms of the following parameters:

- The sign is either -1 or 1.
- The base or radix for exponentiation, an integer greater than 1. This is a constant for a particular representation.
- The *exponent* to which the base is raised. The upper and lower bounds of the exponent value are constants for a particular representation.
 - Sometimes, in the actual bits representing the floating point number, the exponent is biased by adding a constant to it, to make it always be represented as an unsigned quantity. This is only important if you have some reason to pick apart the bit fields making up the floating point number by hand, which is something for which the GNU library provides no support. So this is ignored in the discussion that follows.
- The mantissa or significand, an unsigned integer which is a part of each floating point number.
- The precision of the mantissa. If the base of the representation is b, then the precision is the number of base-b digits in the mantissa. This is a constant for a particular representation.
 - Many floating point representations have an implicit *hidden bit* in the mantissa. This is a bit which is present virtually in the mantissa, but not stored in memory because its value is always 1 in a normalized number. The precision figure (see above) includes any hidden bits.

Again, the GNU library provides no facilities for dealing with such low-level aspects of the representation.

The mantissa of a floating point number actually represents an implicit fraction whose denominator is the base raised to the power of the precision. Since the largest representable mantissa is one less than this denominator, the value of the fraction is always strictly less than 1. The mathematical value of a floating point number is then the product of this fraction, the sign, and the base raised to the exponent.

We say that the floating point number is normalized if the fraction is at least 1/b, where b is the base. In other words, the mantissa would be too large to fit if it were multiplied by the base. Non-normalized numbers are sometimes called denormal; they contain less precision than the representation normally can hold.

If the number is not normalized, then you can subtract 1 from the exponent while multiplying the mantissa by the base, and get another floating point number with the same value. *Normalization* consists of doing this repeatedly until the number is normalized. Two distinct normalized floating point numbers cannot be equal in value.

(There is an exception to this rule: if the mantissa is zero, it is considered normalized. Another exception happens on certain machines where the exponent is as small as the representation can hold. Then it is impossible to subtract 1 from the exponent, so a number may be normalized even if its fraction is less than 1/b.)

A.5.3.2 Floating Point Parameters

These macro definitions can be accessed by including the header file 'float.h' in your program.

Macro names starting with 'FLT_' refer to the float type, while names beginning with 'DBL_' refer to the double type and names beginning with 'LDBL_' refer to the long double type. (Currently GCC does not support long double as a distinct data type, so the values for the 'LDBL_' constants are equal to the corresponding constants for the double type.)

Of these macros, only FLT_RADIX is guaranteed to be a constant expression. The other macros listed here cannot be reliably used in places that require constant expressions, such as '#if' preprocessing directives or in the dimensions of static arrays.

Although the ANSI C standard specifies minimum and maximum values for most of these parameters, the GNU C implementation uses whatever values describe the floating point representation of the target machine. So in principle GNU C actually satisfies the ANSI C requirements only if the target machine is suitable. In practice, all the machines currently supported are suitable.

FLT_ROUNDS

This value characterizes the rounding mode for floating point addition. The following values indicate standard rounding modes:

- -1 The mode is indeterminable.
- 0 Rounding is towards zero.
- 1 Rounding is to the nearest number.
- 2 Rounding is towards positive infinity.
- 3 Rounding is towards negative infinity.

Any other value represents a machine-dependent nonstandard rounding mode.

On most machines, the value is 1, in accordance with the IEEE standard for floating point.

Here is a table showing how certain values round for each possible value of FLT_ROUNDS, if the other aspects of the representation match the IEEE single-precision standard.

	0	1	2	3
1.0000003	1.0	1.0	1.0000012	1.0
1.0000007	1.0	1.00000012	1.0000012	1.0
-1.0000003	-1.0	-1.0	-1.0	-1.00000012
-1.0000007	-1.0	-1.0000012	-1.0	-1.00000012

FLT_RADIX

This is the value of the base, or radix, of exponent representation. This is guaranteed to be a constant expression, unlike the other macros described in this section. The value is 2 on all machines we know of except the IBM 360 and derivatives.

FLT_MANT_DIG

This is the number of base-FLT_RADIX digits in the floating point mantissa for the float data type. The following expression yields 1.0 (even though mathematically it should not) due to the limited number of mantissa digits:

```
float radix = FLT_RADIX;
1.0f + 1.0f / radix / radix / ... / radix
```

where radix appears FLT_MANT_DIG times.

DBL_MANT_DIG LDBL_MANT_DIG

This is the number of base-FLT_RADIX digits in the floating point mantissa for the data types double and long double, respectively.

FLT_DIG

This is the number of decimal digits of precision for the float data type. Technically, if p and b are the precision and base (respectively) for the representation, then the decimal precision q is the maximum number of decimal digits such that any floating point number with q base 10 digits can be rounded to a floating point number with p base p digits and back again, without change to the p decimal digits.

The value of this macro is supposed to be at least 6, to satisfy ANSI C.

DBL_DIG LDBL_DIG

These are similar to FLT_DIG, but for the data types double and long double, respectively. The values of these macros are supposed to be at least 10.

FLT_MIN_EXP

This is the smallest possible exponent value for type float. More precisely, is the minimum negative integer such that the value FLT_RADIX raised to this power minus 1 can be represented as a normalized floating point number of type float.

DBL_MIN_EXP

LDBL_MIN_EXP

These are similar to FLT_MIN_EXP, but for the data types double and long double, respectively.

FLT_MIN_10_EXP

This is the minimum negative integer such that 10 raised to this power minus 1 can be represented as a normalized floating point number of type float. This is supposed to be -37 or even less.

DBL_MIN_10_EXP

LDBL_MIN_10_EXP

These are similar to FLT_MIN_10_EXP, but for the data types double and long double, respectively.

FLT_MAX_EXP

This is the largest possible exponent value for type float. More precisely, this is the maximum positive integer such that value FLT_RADIX raised to this power minus 1 can be represented as a floating point number of type float.

DBL_MAX_EXP

LDBL_MAX_EXP

These are similar to FLT_MAX_EXP, but for the data types double and long double, respectively.

FLT_MAX_10_EXP

This is the maximum positive integer such that 10 raised to this power minus 1 can be represented as a normalized floating point number of type float. This is supposed to be at least 37.

DBL_MAX_10_EXP

LDBL_MAX_10_EXP

These are similar to FLT_MAX_10_EXP, but for the data types double and long double, respectively.

FLT_MAX

The value of this macro is the maximum number representable in type float. It is supposed to be at least 1E+37. The value has type float.

The smallest representable number is - FLT_MAX.

DBL_MAX

LDBL_MAX

These are similar to FLT_MAX, but for the data types double and long double, respectively. The type of the macro's value is the same as the type it describes.

FLT_MIN

The value of this macro is the minimum normalized positive floating point number that is representable in type float. It is supposed to be no more than 1E-37.

DBL_MIN LDBL_MIN

These are similar to FLT_MIN, but for the data types double and long double, respectively. The type of the macro's value is the same as the type it describes.

FLT_EPSILON

This is the minimum positive floating point number of type float such that 1.0 + FLT_EPSILON != 1.0 is true. It's supposed to be no greater than 1E-5.

DBL_EPSILON LDBL EPSILON

These are similar to FLT_EPSILON, but for the data types double and long double, respectively. The type of the macro's value is the same as the type it describes. The values are not supposed to be greater than 1E-9.

A.5.3.3 IEEE Floating Point

Here is an example showing how the floating type measurements come out for the most common floating point representation, specified by the *IEEE Standard for Binary Floating Point Arithmetic* (ANSI/IEEE Std 754-1985). Nearly all computers designed since the 1980s use this format.

The IEEE single-precision float representation uses a base of 2. There is a sign bit, a mantissa with 23 bits plus one hidden bit (so the total precision is 24 base-2 digits), and an 8-bit exponent that can represent values in the range -125 to 128, inclusive.

So, for an implementation that uses this representation for the float data type, appropriate values for the corresponding parameters are:

FLT_RADIX	2
FLT_MANT_DIG	24
FLT_DIG	6
FLT_MIN_EXP	-125
FLT_MIN_10_EXP	-37
FLT_MAX_EXP	128
FLT_MAX_10_EXP	+38
FLT_MIN	1.17549435E-38F
FLT_MAX	3.40282347E+38F
FLT_EPSILON	1.19209290E-07F

Here are the values for the double data type:

DBL_MANT_DIG	53
DBL_DIG	15

A.5.4 Structure Field Offset Measurement

You can use offsetof to measure the location within a structure type of a particular structure member.

size_t offsetof (type, member)

Macro

This expands to a integer constant expression that is the offset of the structure member named member in a the structure type type. For example, offsetof (struct s, elem) is the offset, in bytes, of the member elem in a struct s.

This macro won't work if *member* is a bit field; you get an error from the C compiler in that case.

Appendix B Summary of Library Facilities

This appendix is a complete list of the facilities declared within the header files supplied with the GNU C library. Each entry also lists the standard or other source from which each facility is derived, and tells you where in the manual you can find more information about how to use it.

```

Appendix C Library Maintenance

C.1 How to Install the GNU C Library

Installation of the GNU C library is relatively simple.

You need the latest version of GNU make. Modifying the GNU C Library to work with other make programs would be so hard that we recommend you port GNU make instead. Really.

To configure the GNU C library for your system, run the shell script 'configure' with sh. Use an argument which is the conventional GNU name for your system configuration—for example, 'sparc-sun-sunos4.1', for a Sun 4 running Sunos 4.1. See section "Installing GNU CC" in *Using and Porting GNU CC*, for a full description of standard GNU configuration names.

The GNU C Library currently supports configurations that match the following patterns:

```
sparc-sun-sunos4.n
m68k-hp-bsd4.3
m68k-sun-sunos4.n
m68k-sony-bsd4.3
mips-dec-ultrix4.n
i386-bsd4.3
i386-sysv
i386-sysv4
```

While no other configurations are supported, there are handy aliases for these few. (These aliases work in other GNU software as well.)

```
sun4-sunos4.n
hp320-bsd4.3
sun3-sunos4.n
news
decstation-ultrix
i386-svr4
```

Here are some options that you should specify (if appropriate) when you run configure:

644 The GNU C Library

```
'--with-gnu-ld'
```

Use this option if you plan to use GNU 1d to link programs with the GNU C Library. (We strongly recommend that you do.)

'--with-gnu-as'

Use this option if you plan to use the GNU assembler, gas, when building the GNU C Library. On some systems, the library may not build properly if you do not use gas.

'--nfp'

Use this option if your computer lacks hardware floating point support.

'--prefix=directory'

Install machine-independent data files in subdirectories of 'directory'. (You can also set this in 'configparms'; see below.)

'--exec-prefix=directory'

Install the library and other machine-dependent files in subdirectories of 'directory'. (You can also set this in 'configparms'; see below.)

The simplest way to run **configure** is to do it in the directory that contains the library sources. This prepares to build the library in that very directory.

You can prepare to build the library in some other directory by going to that other directory to run configure. In order to run configure, you will have to specify a directory for it, like this:

```
mkdir ../hp320
cd ../hp320
../src/configure hp320-bsd4.3
```

configure looks for the sources in whatever directory you specified for finding configure itself. It does not matter where in the file system the source and build directories are—as long as you specify the source directory when you run configure, you will get the proper results.

This feature lets you keep sources and binaries in different directories, and that makes it easy to build the library for several different machines from the same set of sources. Simply create a build directory for each target machine, and run **configure** in that directory specifying the target machine's configuration name.

The library has a number of special-purpose configuration parameters. These are defined in the file 'Makeconfig'; see the comments in that file for the details.

But don't edit the file 'Makeconfig' yourself—instead, create a file 'configparms' in the directory where you are building the library, and define in that file the parameters you want to specify. 'configparms' should not be an edited copy of 'Makeconfig'; specify only the parameters that you want to override.

Some of the machine-dependent code for some machines uses extensions in the GNU C compiler, so you may need to compile the library with GCC. (In fact, all of the existing complete ports require GCC.)

The current release of the C library contains some header files that the compiler normally provides: 'stddef.h', 'stdarg.h', and several files with names of the form 'va-machine.h'. The versions of these files that came with older releases of GCC do not work properly with the GNU C library. The 'stddef.h' file in release 2.2 and later of GCC is correct. If you have release 2.2 or later of GCC, use its version of 'stddef.h' instead of the C library's. To do this, put the line 'override stddef.h =' in 'configparms'. The other files are corrected in release 2.3 and later of GCC. 'configure' will automatically detect whether the installed 'stdarg.h' and 'va-machine.h' files are compatible with the C library, and use its own if not.

There is a potential problem with the size_t type and versions of GCC prior to release 2.4. ANSI C requires that size_t always be an unsigned type. For compatibility with existing systems' header files, GCC defines size_t in 'stddef.h' to be whatever type the system's 'sys/types.h' defines it to be. Most Unix systems that define size_t in 'sys/types.h', define it to be a signed type. Some code in the library depends on size_t being an unsigned type, and will not work correctly if it is signed.

The GNU C library code which expects size_t to be unsigned is correct. The definition of size_t as a signed type is incorrect. We plan that in version 2.4, GCC will always define size_t as an unsigned type, and the 'fixincludes' script will massage the system's 'sys/types.h' so as not to conflict with this.

In the meantime, we work around this problem by telling GCC explicitly to use an unsigned type for size_t when compiling the GNU C library. 'configure' will automatically detect what type GCC uses for size_t arrange to override it if necessary.

To build the library, type make lib. This will produce a lot of output, some of which looks like errors from make (but isn't). Look for error messages from make containing '***. Those indicate that something is really wrong. Using the '-w' option to make may make the output easier to understand (this option tells make to print messages telling you what subdirectories it is working on).

646 The GNU C Library

To install the library and header files, type make install, after setting the installation directories in 'configparms'. This will build things if necessary, before installing them.

C.2 Reporting Bugs

There are probably bugs in the GNU C library. If you report them, they will get fixed. If you don't, no one will ever know about them and they will remain unfixed for all eternity, if not longer.

To report a bug, first you must find it. Hopefully, this will be the hard part. Once you've found a bug, make sure it's really a bug. A good way to do this is to see if the GNU C library behaves the same way some other C library does. If so, probably you are wrong and the libraries are right (but not necessarily). If not, one of the libraries is probably wrong.

Once you're sure you've found a bug, try to narrow it down to the smallest test case that reproduces the problem. In the case of a C library, you really only need to narrow it down to one library function call, if possible. This should not be too difficult.

The final step when you have a simple test case is to report the bug. When reporting a bug, send your test case, the results you got, the results you expected, what you think the problem might be (if you've thought of anything), your system type, and the version of the GNU C library which you are using.

If you think you have found some way in which the GNU C library does not conform to the ANSI and POSIX standards (see Section 1.2 [Standards and Portability], page 2), that is definitely a bug. Report it!

Send bug reports to the Internet address 'bug-glibc@prep.ai.mit.edu' or the UUCP path 'mit-eddie!prep.ai.mit.edu!bug-glibc'. If you have other problems with installation, use, or the documentation, please report those as well.

C.3 Adding New Functions

The process of building the library is driven by the makefiles, which make heavy use of special features of GNU make. The makefiles are very complex, and you probably don't want to try to understand them. But what they do is fairly straightforward, and only requires that you define a few variables in the right places.

The library sources are divided into subdirectories, grouped by topic. The 'string' subdirectory has all the string-manipulation functions, 'stdio' has all the standard I/O functions, etc.

Each subdirectory contains a simple makefile, called 'Makefile', which defines a few make variables and then includes the global makefile 'Rules' with a line like:

include ../Rules

The basic variables that a subdirectory makefile defines are:

subdir The name of the subdirectory, for example 'stdio'. This variable must be defined.

headers The names of the header files in this section of the library, such as 'stdio.h'.

routines

The names of the modules (source files) in this section of the library. These should be simple names, such as 'strlen' (rather than complete file names, such as 'strlen.c'). Use routines for modules that define functions in the library, and aux for auxiliary modules containing things like data definitions. But the values of routines and aux

are just concatenated, so there really is no practical difference.

The names of test programs for this section of the library. These should be simple names, such as 'tester' (rather than complete file names, such as 'tester.c'). 'make tests' will build and run all the test programs. If a test program needs input, put the test data in a file called 'test-program.input'; it will be given to the test program on its standard input. If a test program wants to be run with arguments, put

the arguments (all on a single line) in a file called 'test-program.args'.

The names of "other" programs associated with this section of the library. These are programs which are not tests per se, but are other small programs included with the

library. They are built by 'make others'.

install-lib

install-data

Files to be installed by 'make install'. Things listed in 'install-lib' are installed in the directory specified by 'libdir' in 'Makeconfig' (see Section C.1 [Installation], page 643). Files listed in install-data are installed in the directory specified by 'datadir' in 'configparms' or 'Makeconfig'. Files listed in install are installed in the directory specified by 'bindir' in 'Makeconfig'.

distribute

Other files from this subdirectory which should be put into a distribution tar file. You need not list here the makefile itself or the source and header files listed in the other

standard variables. Only define distribute if there are files used in an unusual way that should go into the distribution.

generated

Files which are generated by 'Makefile' in this subdirectory. These files will be removed by 'make clean', and they will never go into a distribution.

extra-objs

Extra object files which are built by 'Makefile' in this subdirectory. This should be a list of file names like 'foo.o'; the files will actually be found in whatever directory object files are being built in. These files will be removed by 'make clean'. This variable is used for secondary object files needed to build others or tests.

C.4 Porting the GNU C Library

The GNU C library is written to be easily portable to a variety of machines and operating systems. Machine- and operating system-dependent functions are well separated to make it easy to add implementations for new machines or operating systems. This section describes the layout of the library source tree and explains the mechanisms used to select machine-dependent code to use.

All the machine-dependent and operating system-dependent files in the library are in the subdirectory 'sysdeps' under the top-level library source directory. This directory contains a hierarchy of subdirectories (see Section C.4.1 [Hierarchy Conventions], page 650).

Each subdirectory of 'sysdeps' contains source files for a particular machine or operating system, or for a class of machine or operating system (for example, systems by a particular vendor, or all machines that use IEEE 754 floating-point format). A configuration specifies an ordered list of these subdirectories. Each subdirectory implicitly appends its parent directory to the list. For example, specifying the list 'unix/bsd/vax' is equivalent to specifying the list 'unix/bsd/vax unix/bsd unix'. A subdirectory can also specify that it implies other subdirectories which are not directly above it in the directory hierarchy. If the file 'Implies' exists in a subdirectory, it lists other subdirectories of 'sysdeps' which are appended to the list, appearing after the subdirectory containing the 'Implies' file. Lines in an 'Implies' file that begin with a '#' character are ignored as comments. For example, 'unix/bsd/Implies' contains:

BSD has Internet-related things. unix/inet

and 'unix/Implies' contains:

posix

So the final list is 'unix/bsd/vax unix/bsd vax unix/inet unix posix'.

'sysdeps' has two "special" subdirectories, called 'generic' and 'stub'. These two are always implicitly appended to the list of subdirectories (in that order), so you needn't put them in an 'Implies' file, and you should not create any subdirectories under them. 'generic' is for things that can be implemented in machine-independent C, using only other machine-independent functions in the C library. 'stub' is for stub versions of functions which cannot be implemented on a particular machine or operating system. The stub functions always return an error, and set errno to ENOSYS (Function not implemented). See Chapter 2 [Error Reporting], page 15.

A source file is known to be system-dependent by its having a version in 'generic' or 'stub'; every system-dependent function should have either a generic or stub implementation (there is no point in having both).

If you come across a file that is in one of the main source directories ('string', 'stdio', etc.), and you want to write a machine- or operating system-dependent version of it, move the file into 'sysdeps/generic' and write your new implementation in the appropriate system-specific subdirectory. Note that if a file is to be system-dependent, it must not appear in one of the main source directories.

There are a few special files that may exist in each subdirectory of 'sysdeps':

'Makefile'

A makefile for this machine or operating system, or class of machine or operating system. This file is included by the library makefile 'Makerules', which is used by the top-level makefile and the subdirectory makefiles. It can change the variables set in the including makefile or add new rules. It can use GNU make conditional directives based on the variable 'subdir' (see above) to select different sets of variables and rules for different sections of the library. It can also set the make variable 'sysdep-routines', to specify extra modules to be included in the library. You should use 'sysdep-routines' rather than adding modules to 'routines' because the latter is used in determining what to distribute for each subdirectory of the main source tree.

Each makefile in a subdirectory in the ordered list of subdirectories to be searched is included in order. Since several system-dependent makefiles may be included, each should append to 'sysdep-routines' rather than simply setting it:

sysdep-routines := \$(sysdep-routines) foo bar

'Subdirs' This file contains the names of new whole subdirectories under the top-level library source tree that should be included for this system. These subdirectories are treated just like the system-independent subdirectories in the library source tree, such as 'stdio' and 'math'.

Use this when there are whole new sets of routines and header files that should go into the library for the system this subdirectory of 'sysdeps' implements. For example, 'sysdeps/unix/inet/Subdirs' contains 'inet'; the 'inet' directory contains various network-oriented operations which only make sense to put in the library on systems that support the Internet.

'Dist' This file contains the names of files (relative the the subdirectory of 'sysdeps' in which it appears) which should be included in the distribution. List any new files used by rules in the 'Makefile' in the same directory, or header files used by the source files in that directory. You don't need to list files that are implementations (either C or assembly source) of routines whose names are given in the machine-independent makefiles in the main source tree.

That is the general system for how system-dependencies are isolated. The next section explains how to decide what directories in 'sysdeps' to use. Section C.4.2 [Porting to Unix], page 652, has some tips on porting the library to Unix variants.

C.4.1 The Layout of the 'sysdeps' Directory Hierarchy

A GNU configuration name has three parts: the CPU type, the manufacturer's name, and the operating system. 'configure' uses these to pick the list of system-dependent directories to look for. If the '--nfp' option is not passed to 'configure', the directory 'machine/fpu' is also used. The operating system often has a base operating system; for example, if the operating system is 'sunos4.1', the base operating system is 'unix/bsd'. The algorithm used to pick the list of directories is simple: 'configure' makes a list of the base operating system, manufacturer, CPU type, and operating system, in that order. It then concatenates all these together with slashes in between, to produce a directory name; for example, the configuration 'sparc-sun-sunos4.1' results in 'unix/bsd/sun/sparc/sunos4.1'. 'configure' then tries removing each element of the list in turn, so 'unix/bsd/sparc' and 'sun/sparc' are also tried, among others. Since the precise version number of the operating system is often not important, and it would be very inconvenient, for ex-

ample, to have identical 'sunos4.1.1' and 'sunos4.1.2' directories, 'configure' tries successively less specific operating system names by removing trailing suffixes starting with a period.

Here is the complete list of directories that would be tried for the configuration 'sparc-sun-sunos4.1':

```
sparc/fpu
unix/bsd/sun/sunos4.1/sparc
unix/bsd/sun/sunos4.1
unix/bsd/sun/sunos4/sparc
unix/bsd/sun/sunos4
unix/bsd/sun/sparc
unix/bsd/sun
unix/bsd/sunos4.1/sparc
unix/bsd/sunos4.1
unix/bsd/sunos4/sparc
unix/bsd/sunos4
unix/bsd/sparc
unix/bsd
sun/sunos4.1/sparc
sun/sunos4.1
sun/sunos4/sparc
sun/sunos4
sun/sparc
sun
sunos4.1/sparc
sunos4.1
sunos4/sparc
sunos4
sparc
```

Different machine architectures are generally at the top level of the 'sysdeps' directory tree. For example, 'sysdeps/sparc' and 'sysdeps/m68k'. These contain files specific to those machine architectures, but not specific to any particular operating system. There might be subdirectories for specializations of those architectures, such as 'sysdeps/m68k/68020'. Code which is specific to the floating-point coprocessor used with a particular machine should go in 'sysdeps/machine/fpu'.

There are a few directories at the top level of the 'sysdeps' hierarchy that are not for particular machine architectures.

'generic'

'stub' As described above (see Section C.4 [Porting], page 648), these are the two subdirectories that every configuration implicitly uses after all others.

'ieee754' This directory is for code using the IEEE 754 floating-point format, where the C type float is IEEE 754 single-precision format, and double is IEEE 754 double-precision format. Usually this directory is referred to in the 'Implies' file in a machine architecture-specific directory, such as 'm68k/Implies'.

'posix' This directory contains implementations of things in the library in terms of POSIX.1 functions. This includes some of the POSIX.1 functions themselves. Of course, POSIX.1 cannot be completely implemented in terms of itself, so a configuration using just 'posix' cannot be complete.

'unix' This is the directory for Unix-like things. See See Section C.4.2 [Porting to Unix], page 652. 'unix' implies 'posix'. There are some special-purpose subdirectories of 'unix':

'unix/common'

This directory is for things common to both BSD and System V release 4. Both 'unix/bsd' and 'unix/sysv/sysv4' imply 'unix/common'.

'unix/inet'

This directory is for socket and related functions on Unix systems. The 'inet' top-level subdirectory is enabled by 'unix/inet/Subdirs'. 'unix/common' implies 'unix/inet'.

'mach' This is the directory for things based on the Mach microkernel from CMU (including the GNU operating system). Other basic operating systems (VMS, for example) would have their own directories at the top level of the 'sysdeps' hierarchy, parallel to 'unix' and 'mach'.

C.4.2 Porting the GNU C Library to Unix Systems

Most Unix systems are fundamentally very similar. There are variations between different machines, and variations in what facilities are provided by the kernel. But the interface to the operating system facilities is, for the most part, pretty uniform and simple.

The code for Unix systems is in the directory 'unix', at the top level of the 'sysdeps' hierarchy. This directory contains subdirectories (and subdirectory trees) for various Unix variants.

The functions which are system calls in most Unix systems are implemented in assembly code in files in 'sysdeps/unix'. These files are named with a suffix of '.S'; for example, '__open.S'. Files ending in '.S' are run through the C preprocessor before being fed to the assembler.

These files all use a set of macros that should be defined in 'sysdep.h'. The 'sysdep.h' file in 'sysdeps/unix' partially defines them; a 'sysdep.h' file in another directory must finish defining them for the particular machine and operating system variant. See 'sysdeps/unix/sysdep.h' and the machine-specific 'sysdep.h' implementations to see what these macros are and what they should do.

The system-specific makefile for the 'unix' directory, 'sysdeps/unix/Makefile', gives rules to generate several files from the Unix system you are building the library on (which is assumed to be the target system you are building the library for). All the generated files are put in the directory where the object files are kept; they should not affect the source tree itself. The files generated are 'ioctls.h', 'errnos.h', 'sys/param.h', and 'errlist.c' (for the 'stdio' section of the library).

C.5 Contributors to the GNU C Library

The GNU C library was written almost entirely by Roland McGrath. Some parts of the library were contributed by other people.

- The getopt function and related code were written by Richard Stallman, David J. MacKenzie, and Roland McGrath.
- Most of the math functions are taken from 4.4 BSD; they have been modified only slightly to work with the GNU C library. The Internet-related code (most of the 'inet' subdirectory) and several other miscellaneous functions and header files have been included with little or no modification.

All code incorporated from 4.4 BSD is under the following copyright:

Copyright © 1991 Regents of the University of California. All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:

- 1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.
- 2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in the documentation and/or other materials provided with the distribution.
- 3. All advertising materials mentioning features or use of this software must display the following acknowledgement:

This product includes software developed by the University of California, Berkeley and its contributors.

4. Neither the name of the University nor the names of its contributors may be used to endorse or promote products derived from this software without specific prior written permission.

THIS SOFTWARE IS PROVIDED BY THE REGENTS AND CONTRIBUTORS "AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE REGENTS OR CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL, EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY OF LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

- The random number generation functions random, srandom, setstate and initstate, which are also the basis for the rand and srand functions, were written by Earl T. Cohen for the University of California at Berkeley and are copyrighted by the Regents of the University of California. They have undergone minor changes to fit into the GNU C library and to fit the ANSI C standard, but the functional code is Berkeley's.
- The merge sort function qsort was written by Michael J. Haertel.
- The quick sort function used as a fallback by qsort was written by Douglas C. Schmidt.
- The memory allocation functions malloc, realloc and free and related code were written by Michael J. Haertel.
- Fast implementations of many of the string functions (memcpy, strlen, etc.) were written by Torbjörn Granlund.
- Some of the support code for Mach is taken from Mach 3.0 by CMU, and is under the following copyright terms:

Mach Operating System Copyright © 1991,1990,1989 Carnegie Mellon University All Rights Reserved.

Permission to use, copy, modify and distribute this software and its documentation is hereby granted, provided that both the copyright notice and this permission notice appear in all copies of the software, derivative works or modified versions, and any portions thereof, and that both notices appear in supporting documentation. Carnegie Mellon allows free use of this software in its "as is" condition. Carnegie Mellon disclaims any liability of any kind for any damages whatsoever resulting from the use of this software.

Carnegie Mellon requests users of this software to return to

Software Distribution Coordinator School of Computer Science Carnegie Mellon University Pittsburgh PA 15213-3890 or 'Software.Distribution@CS.CMU.EDU' any improvements or extensions that they make and grant Carnegie Mellon the rights to redistribute these changes.

- The 'tar.h' header file was written by David J. MacKenzie.
- The port to the MIPS DECStation running Ultrix 4 (mips-dec-ultrix4) was contributed by Brendan Kehoe and Ian Lance Taylor.
- The DES encryption function crypt and related functions were contributed by Michael Glad.
- The ftw function was contributed by Ian Lance Taylor.
- The code to support SunOS shared libraries was contributed by Tom Quinn.
- The mktime function was contributed by Noel Cragg.
- The port to the Sequent Symmetry running Dynix version 3 (i386-sequent-bsd) was contributed by Jason Merrill.

Appendix D GNU LIBRARY GENERAL PUBLIC LICENSE

Version 2, June 1991

Copyright © 1991 Free Software Foundation, Inc. 675 Mass Ave, Cambridge, MA 02139, USA Everyone is permitted to copy and distribute verbatim copies of this license document, but changing it is not allowed.

[This is the first released version of the library GPL. It is numbered 2 because it goes with version 2 of the ordinary GPL.]

Preamble

The licenses for most software are designed to take away your freedom to share and change it. By contrast, the GNU General Public Licenses are intended to guarantee your freedom to share and change free software—to make sure the software is free for all its users.

This license, the Library General Public License, applies to some specially designated Free Software Foundation software, and to any other libraries whose authors decide to use it. You can use it for your libraries, too.

When we speak of free software, we are referring to freedom, not price. Our General Public Licenses are designed to make sure that you have the freedom to distribute copies of free software (and charge for this service if you wish), that you receive source code or can get it if you want it, that you can change the software or use pieces of it in new free programs; and that you know you can do these things.

To protect your rights, we need to make restrictions that forbid anyone to deny you these rights or to ask you to surrender the rights. These restrictions translate to certain responsibilities for you if you distribute copies of the library, or if you modify it.

For example, if you distribute copies of the library, whether gratis or for a fee, you must give the recipients all the rights that we gave you. You must make sure that they, too, receive or can get the source code. If you link a program with the library, you must provide complete object files to the recipients so that they can relink them with the library, after making changes to the library and recompiling it. And you must show them these terms so they know their rights.

Our method of protecting your rights has two steps: (1) copyright the library, and (2) offer you this license which gives you legal permission to copy, distribute and/or modify the library.

Also, for each distributor's protection, we want to make certain that everyone understands that there is no warranty for this free library. If the library is modified by someone else and passed on, we want its recipients to know that what they have is not the original version, so that any problems introduced by others will not reflect on the original authors' reputations.

Finally, any free program is threatened constantly by software patents. We wish to avoid the danger that companies distributing free software will individually obtain patent licenses, thus in effect transforming the program into proprietary software. To prevent this, we have made it clear that any patent must be licensed for everyone's free use or not licensed at all.

Most GNU software, including some libraries, is covered by the ordinary GNU General Public License, which was designed for utility programs. This license, the GNU Library General Public License, applies to certain designated libraries. This license is quite different from the ordinary one; be sure to read it in full, and don't assume that anything in it is the same as in the ordinary license.

The reason we have a separate public license for some libraries is that they blur the distinction we usually make between modifying or adding to a program and simply using it. Linking a program with a library, without changing the library, is in some sense simply using the library, and is analogous to running a utility program or application program. However, in a textual and legal sense, the linked executable is a combined work, a derivative of the original library, and the ordinary General Public License treats it as such.

Because of this blurred distinction, using the ordinary General Public License for libraries did not effectively promote software sharing, because most developers did not use the libraries. We concluded that weaker conditions might promote sharing better.

However, unrestricted linking of non-free programs would deprive the users of those programs of all benefit from the free status of the libraries themselves. This Library General Public License is intended to permit developers of non-free programs to use free libraries, while preserving your freedom as a user of such programs to change the free libraries that are incorporated in them. (We have not seen how to achieve this as regards changes in header files, but we have achieved it as regards changes in the actual functions of the Library.) The hope is that this will lead to faster development of free libraries.

The precise terms and conditions for copying, distribution and modification follow. Pay close attention to the difference between a "work based on the library" and a "work that uses the library". The former contains code derived from the library, while the latter only works together with the library.

Note that it is possible for a library to be covered by the ordinary General Public License rather than by this special one.

TERMS AND CONDITIONS FOR COPYING, DISTRIBUTION AND MODIFICATION

1. This License Agreement applies to any software library which contains a notice placed by the copyright holder or other authorized party saying it may be distributed under the terms of this Library General Public License (also called "this License"). Each licensee is addressed as "you".

A "library" means a collection of software functions and/or data prepared so as to be conveniently linked with application programs (which use some of those functions and data) to form executables.

The "Library", below, refers to any such software library or work which has been distributed under these terms. A "work based on the Library" means either the Library or any derivative work under copyright law: that is to say, a work containing the Library or a portion of it, either verbatim or with modifications and/or translated straightforwardly into another language. (Hereinafter, translation is included without limitation in the term "modification".)

"Source code" for a work means the preferred form of the work for making modifications to it. For a library, complete source code means all the source code for all modules it contains, plus any associated interface definition files, plus the scripts used to control compilation and installation of the library.

Activities other than copying, distribution and modification are not covered by this License; they are outside its scope. The act of running a program using the Library is not restricted, and output from such a program is covered only if its contents constitute a work based on the Library (independent of the use of the Library in a tool for writing it). Whether that is true depends on what the Library does and what the program that uses the Library does.

2. You may copy and distribute verbatim copies of the Library's complete source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice and disclaimer of warranty; keep intact all the notices that refer to this License and to the absence of any warranty; and distribute a copy of this License along with the Library.

You may charge a fee for the physical act of transferring a copy, and you may at your option offer warranty protection in exchange for a fee.

- 3. You may modify your copy or copies of the Library or any portion of it, thus forming a work based on the Library, and copy and distribute such modifications or work under the terms of Section 1 above, provided that you also meet all of these conditions:
 - a. The modified work must itself be a software library.
 - b. You must cause the files modified to carry prominent notices stating that you changed the files and the date of any change.
 - c. You must cause the whole of the work to be licensed at no charge to all third parties under the terms of this License.
 - d. If a facility in the modified Library refers to a function or a table of data to be supplied by an application program that uses the facility, other than as an argument passed when the facility is invoked, then you must make a good faith effort to ensure that, in the event an application does not supply such function or table, the facility still operates, and performs whatever part of its purpose remains meaningful.

(For example, a function in a library to compute square roots has a purpose that is entirely well-defined independent of the application. Therefore, Subsection 2d requires that any application-supplied function or table used by this function must be optional: if the application does not supply it, the square root function must still compute square roots.)

These requirements apply to the modified work as a whole. If identifiable sections of that work are not derived from the Library, and can be reasonably considered independent and separate works in themselves, then this License, and its terms, do not apply to those sections when you distribute them as separate works. But when you distribute the same sections as part of a whole which is a work based on the Library, the distribution of the whole must be on the terms of this License, whose permissions for other licensees extend to the entire whole, and thus to each and every part regardless of who wrote it.

Thus, it is not the intent of this section to claim rights or contest your rights to work written entirely by you; rather, the intent is to exercise the right to control the distribution of derivative or collective works based on the Library.

In addition, mere aggregation of another work not based on the Library with the Library (or with a work based on the Library) on a volume of a storage or distribution medium does not bring the other work under the scope of this License.

4. You may opt to apply the terms of the ordinary GNU General Public License instead of this License to a given copy of the Library. To do this, you must alter all the notices that refer to this License, so that they refer to the ordinary GNU General Public License, version 2, instead of to this License. (If a newer version than version 2 of the ordinary GNU General Public License has appeared, then you can specify that version instead if you wish.) Do not make any other change in these notices.

Once this change is made in a given copy, it is irreversible for that copy, so the ordinary GNU General Public License applies to all subsequent copies and derivative works made from that copy.

This option is useful when you wish to copy part of the code of the Library into a program that is not a library.

- 5. You may copy and distribute the Library (or a portion or derivative of it, under Section 2) in object code or executable form under the terms of Sections 1 and 2 above provided that you accompany it with the complete corresponding machine-readable source code, which must be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange.
 - If distribution of object code is made by offering access to copy from a designated place, then offering equivalent access to copy the source code from the same place satisfies the requirement to distribute the source code, even though third parties are not compelled to copy the source along with the object code.
- 6. A program that contains no derivative of any portion of the Library, but is designed to work with the Library by being compiled or linked with it, is called a "work that uses the Library". Such a work, in isolation, is not a derivative work of the Library, and therefore falls outside the scope of this License.

However, linking a "work that uses the Library" with the Library creates an executable that is a derivative of the Library (because it contains portions of the Library), rather than a "work that uses the library". The executable is therefore covered by this License. Section 6 states terms for distribution of such executables.

When a "work that uses the Library" uses material from a header file that is part of the Library, the object code for the work may be a derivative work of the Library even though the source code is not. Whether this is true is especially significant if the work can be linked without the Library, or if the work is itself a library. The threshold for this to be true is not precisely defined by law.

If such an object file uses only numerical parameters, data structure layouts and accessors, and small macros and small inline functions (ten lines or less in length), then the use of the object file is unrestricted, regardless of whether it is legally a derivative work. (Executables containing this object code plus portions of the Library will still fall under Section 6.)

Otherwise, if the work is a derivative of the Library, you may distribute the object code for the work under the terms of Section 6. Any executables containing that work also fall under Section 6, whether or not they are linked directly with the Library itself.

7. As an exception to the Sections above, you may also compile or link a "work that uses the Library" with the Library to produce a work containing portions of the Library, and distribute that work under terms of your choice, provided that the terms permit modification of the work for the customer's own use and reverse engineering for debugging such modifications.

You must give prominent notice with each copy of the work that the Library is used in it and that the Library and its use are covered by this License. You must supply a copy of this License. If the work during execution displays copyright notices, you must include the copyright notice for the Library among them, as well as a reference directing the user to the copy of this License. Also, you must do one of these things:

- a. Accompany the work with the complete corresponding machine-readable source code for the Library including whatever changes were used in the work (which must be distributed under Sections 1 and 2 above); and, if the work is an executable linked with the Library, with the complete machine-readable "work that uses the Library", as object code and/or source code, so that the user can modify the Library and then relink to produce a modified executable containing the modified Library. (It is understood that the user who changes the contents of definitions files in the Library will not necessarily be able to recompile the application to use the modified definitions.)
- b. Accompany the work with a written offer, valid for at least three years, to give the same user the materials specified in Subsection 6a, above, for a charge no more than the cost of performing this distribution.
- c. If distribution of the work is made by offering access to copy from a designated place, offer equivalent access to copy the above specified materials from the same place.
- d. Verify that the user has already received a copy of these materials or that you have already sent this user a copy.

For an executable, the required form of the "work that uses the Library" must include any data and utility programs needed for reproducing the executable from it. However, as a special exception, the source code distributed need not include anything that is normally distributed (in either source or binary form) with the major components (compiler, kernel, and so on) of the operating system on which the executable runs, unless that component itself accompanies the executable.

It may happen that this requirement contradicts the license restrictions of other proprietary libraries that do not normally accompany the operating system. Such a contradiction means you cannot use both them and the Library together in an executable that you distribute.

- 8. You may place library facilities that are a work based on the Library side-by-side in a single library together with other library facilities not covered by this License, and distribute such a combined library, provided that the separate distribution of the work based on the Library and of the other library facilities is otherwise permitted, and provided that you do these two things:
 - a. Accompany the combined library with a copy of the same work based on the Library, uncombined with any other library facilities. This must be distributed under the terms of the Sections above.
 - b. Give prominent notice with the combined library of the fact that part of it is a work based

on the Library, and explaining where to find the accompanying uncombined form of the same work.

- 9. You may not copy, modify, sublicense, link with, or distribute the Library except as expressly provided under this License. Any attempt otherwise to copy, modify, sublicense, link with, or distribute the Library is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so long as such parties remain in full compliance.
- 10. You are not required to accept this License, since you have not signed it. However, nothing else grants you permission to modify or distribute the Library or its derivative works. These actions are prohibited by law if you do not accept this License. Therefore, by modifying or distributing the Library (or any work based on the Library), you indicate your acceptance of this License to do so, and all its terms and conditions for copying, distributing or modifying the Library or works based on it.
- 11. Each time you redistribute the Library (or any work based on the Library), the recipient automatically receives a license from the original licensor to copy, distribute, link with or modify the Library subject to these terms and conditions. You may not impose any further restrictions on the recipients' exercise of the rights granted herein. You are not responsible for enforcing compliance by third parties to this License.
- 12. If, as a consequence of a court judgment or allegation of patent infringement or for any other reason (not limited to patent issues), conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot distribute so as to satisfy simultaneously your obligations under this License and any other pertinent obligations, then as a consequence you may not distribute the Library at all. For example, if a patent license would not permit royalty-free redistribution of the Library by all those who receive copies directly or indirectly through you, then the only way you could satisfy both it and this License would be to refrain entirely from distribution of the Library.

If any portion of this section is held invalid or unenforceable under any particular circumstance, the balance of the section is intended to apply, and the section as a whole is intended to apply in other circumstances.

It is not the purpose of this section to induce you to infringe any patents or other property right claims or to contest validity of any such claims; this section has the sole purpose of protecting the integrity of the free software distribution system which is implemented by public license practices. Many people have made generous contributions to the wide range of software distributed through that system in reliance on consistent application of that system; it is up to the author/donor to decide if he or she is willing to distribute software through any other system and a licensee cannot impose that choice.

This section is intended to make thoroughly clear what is believed to be a consequence of the rest of this License.

- 13. If the distribution and/or use of the Library is restricted in certain countries either by patents or by copyrighted interfaces, the original copyright holder who places the Library under this License may add an explicit geographical distribution limitation excluding those countries, so that distribution is permitted only in or among countries not thus excluded. In such case, this License incorporates the limitation as if written in the body of this License.
- 14. The Free Software Foundation may publish revised and/or new versions of the Library General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

 Each version is given a distinguishing version number. If the Library specifies a version number of this License which applies to it and "any later version", you have the option of following the terms and conditions either of that version or of any later version published by the Free Software Foundation. If the Library does not specify a license version number, you may choose
- 15. If you wish to incorporate parts of the Library into other free programs whose distribution conditions are incompatible with these, write to the author to ask for permission. For software which is copyrighted by the Free Software Foundation, write to the Free Software Foundation; we sometimes make exceptions for this. Our decision will be guided by the two goals of preserving the free status of all derivatives of our free software and of promoting the sharing and reuse of software generally.

any version ever published by the Free Software Foundation.

NO WARRANTY

- 16. BECAUSE THE LIBRARY IS LICENSED FREE OF CHARGE, THERE IS NO WARRANTY FOR THE LIBRARY, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE LIBRARY "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE LIBRARY IS WITH YOU. SHOULD THE LIBRARY PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.
- 17. IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MAY MODIFY AND/OR REDISTRIBUTE THE LIBRARY AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE LIBRARY (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE LIBRARY TO OPERATE WITH ANY OTHER SOFTWARE), EVEN

IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

END OF TERMS AND CONDITIONS

How to Apply These Terms to Your New Libraries

If you develop a new library, and you want it to be of the greatest possible use to the public, we recommend making it free software that everyone can redistribute and change. You can do so by permitting redistribution under these terms (or, alternatively, under the terms of the ordinary General Public License).

To apply these terms, attach the following notices to the library. It is safest to attach them to the start of each source file to most effectively convey the exclusion of warranty; and each file should have at least the "copyright" line and a pointer to where the full notice is found.

one line to give the library's name and an idea of what it does. Copyright (C) year name of author

This library is free software; you can redistribute it and/or modify it under the terms of the GNU Library General Public License as published by the Free Software Foundation; either version 2 of the License, or (at your option) any later version.

This library is distributed in the hope that it will be useful, but WITHOUT ANY WARRANTY; without even the implied warranty of MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE. See the GNU Library General Public License for more details.

You should have received a copy of the GNU Library General Public License along with this library; if not, write to the Free Software Foundation, Inc., 675 Mass Ave, Cambridge, MA 02139, USA.

Also add information on how to contact you by electronic and paper mail.

You should also get your employer (if you work as a programmer) or your school, if any, to sign a "copyright disclaimer" for the library, if necessary. Here is a sample; alter the names:

Yoyodyne, Inc., hereby disclaims all copyright interest in the library 'Frob' (a library for tweaking knobs) written by James Random Hacker.

signature of Ty Coon, 1 April 1990 Ty Coon, President of Vice

That's all there is to it!

_	array comparison functions
_POSIX_OPTION_ORDER environment variable.	array copy functions
475	array search function
	array sort function
4	ASCII character
4.x BSD Unix	assertions
	attributes of a file
A	automatic allocation
abort signal	automatic freeing
aborting a program	automatic storage with variable size 54
absolute file name	
absolute me name	В
accepting connections	background job
access permission for a file	background job, launching
access, testing for	base (of floating point number)
accessing directories	basic byte sequence
address of socket	baud rate
alarm signal	Berkeley Unix
alarms, setting	bias (of floating point number exponent)
alignment (in obstacks)	big-endian
alignment (with malloc)	binary I/O to a stream
alloca disadvantages	binary search function (for arrays)
alloca function	binary stream
allocation (obstacks)	binding a socket address
allocation hooks, for malloc	blank character
allocation of memory with malloc	block I/O to a stream
allocation size of string	blocked signals
allocation statistics	blocked signals, checking for
alphabetic character	blocking signals
alphanumeric character	blocking signals, in a handler
ANSI C	break condition, detecting
append mode (file status flag)	break condition, generating
append-access files	breaking a string into tokens
argc (program argument count)	broken pipe signal
argument promotion	broken-down time
arguments (variadic functions)	BSD compatibility library
arguments, how many	BSD Unix
argy (program argument vector)	buffering of streams
arithmetic expansion	buffering, controlling
<u>r</u>	0)0

The GNU C Library

bus error	409	communication style (of a socket)	269
byte order conversion, for socket	287	comparing strings and arrays	72
byte stream	269	Comparison Function	107
		$concatenating \ strings \ \\$	67
\mathbf{C}		connecting a socket	295
		connection	295
calendar time		consistency checking	563
calendar time and broken-down time		consistency checking, of heap	36
calling variadic functions		continue signal	412
canonical input processing		${\bf control\ character}$	63
capacity limits, POSIX	545	control operations on files	219
carrier detect	330	controlling process	497
case conversion of characters		controlling terminal	496
catching signals	405	controlling terminal, access to	497
categories for locales	98	controlling terminal, determining	516
change working directory		conversion specifications (printf)	150
changing the locale	99	conversion specifications (scanf)	174
changing the size of a block $({\tt malloc}) \dots \dots$	34	converting byte order	287
changing the size of a block (obstacks) $\ldots \ldots \ldots$		converting case of characters	63
channels	213	converting extended characters	90
character case conversion	63	converting extended strings	88
character code	88	converting file descriptor to stream	212
character predicates	61	converting floats to integers	
character testing	61	converting group ID to group name	537
checking for pending signals	451	converting group name to group ID	537

killing a process	441	0 1 2 11 2 2	

The GNU C Library

login name	non-local exit, from signal handler 428
login name, determining	non-local exits
LOGNAME environment variable	noncanonical input processing 323
long jumps	normalization functions (floating-point) 361
long-named options	normalized floating point number 577
longjmp	not a number
loss of data on sockets	null character
lower-case character	null pointer constant 572
	number of arguments passed 567
M	number syntax, parsing
macros	numeric value formatting 102
main function	
malloc function	O
mantissa (of floating point number)	obstack status
matching failure, in scanf	obstacks40
maximum field width (scanf)	opening a file
measurements of floating types 576	opening a file descriptor
memory allocation	opening a pipe
memory usage warnings	opening a socket
merging of signals	opening a socket pair 294
MIN termios slot	opening a stream
minimum field width (printf)	optional arguments
mixing descriptors and streams	optional POSIX features
modem disconnect	orphaned process group 498
modem status lines	out-of-band data 306
monetary value formatting	output conversions, for printf
multibyte character, length of	output possible signal
multibyte characters	owner of a file 252
multiple names for one file	
multiplexing input	P
	packet
N	page boundary 36
name of running program	parent directory
name of socket	parent process
name space	parity checking 327
names of signals	parsing a template string
namespace (of socket)	parsing numbers (in formatted input) 366
NaN	parsing program arguments 465
network byte order	parsing tokens from a string 80
network number	password database
network protocol	PATH environment variable 474
networks database	pause function
non-blocking mode (file status flag) 204	peeking at input

Concept Index 673

pending signals	program name
pending signals, checking for 451	program termination
permission to access a file	program termination signals 409
persona	programming your own streams
pi (trigonometric constant)	protocol (of socket)
pipe	protocol family
pipe signal	protocols database
pipe to a subprocess	prototypes for variadic functions 566
port number	pseudo-random numbers
positioning a file descriptor 209	punctuation character
positioning a stream	pushing input back
POSIX 3	
POSIX capacity limits 545	Q
POSIX optional features 547	quick sort function (for arrays)
POSIX.1 3	QUIT character
POSIX.2 3	quit signal
power functions	quote removal
precision (of floating point number) 577	quote femovar125
precision (printf)	D
predicates on arrays 72	R
predicates on characters	race conditions, relating to job control 504
predicates on strings	race conditions, relating to signals 430
printing character	radix (of floating point number) 577
priority of a process	raising signals
process	random numbers
process completion	random-access files
process group functions 515	range error 349
process group ID	range of integer type 574
process group leader	read lock
process groups	reading from a directory
process ID	reading from a file descriptor 206
process image	reading from a socket
process lifetime	reading from a stream, by blocks
process priority	reading from a stream, by characters 144
process signal mask	reading from a stream, formatted
process termination	real group ID
processor time	real user ID 522
profiling alarm signal 411	real-time timer
profiling timer	receiving datagrams
program argument syntax	record locking
program arguments	redirecting input and output 220
program arguments, parsing	reentrant functions
program error signals	relative file name
- ~	relocating memory allocator 57

remainder functions	signal 403
removal of quotes	signal action
removing a file	signal actions
removing macros that shadow functions 6	signal flags
renaming a file	signal function
reporting bugs	signal handler function 425
reporting errors	signal mask
REPRINT character	signal messages 415
reserved names	signal names
resource limits	signal number 406
restrictions on signal handler functions	signal set
root directory	signal stack
rounding functions	signals, generating
running a command	significand (of floating point number) 577
	SIGTTIN, from background job 497
g	SIGTTOU, from background job 497
\mathbf{S}	size of string
scanning the group list	socket
scanning the user list 535	socket address (name) binding
search function (for arrays)	socket domain 270
search functions (for strings)	socket namespace
seed (for random numbers)	socket option level
seeking on a file descriptor	socket options
seeking on a stream	socket pair
segmentation violation	socket protocol
sending a datagram	socket shutdown
sending signals	socket, client actions
sequential-access files	socket, closing
server	socket, connecting
services database	socket, creating
session	socket, initiating a connection
session leader	sockets, accepting connections
setting an alarm	sockets, listening
setuid programs523	sockets, server actions 296
setuid programs and file access	soft link
shadowing functions with macros 6	sort function (for arrays)
shared lock	special files
shell	specified action (for a signal)
shrinking objects	square root function
shutting down a socket	stable sorting
sigaction flags	standard dot notation, for Internet addresses 280
sigaction function	standard dot notation, for interior diditions of the new teachers
	standard environment variables
SIGCHLD, handling of 509	standard environment variables

Concept Index 675

standard error stream	supplementary group IDs 522
standard file descriptors	SUSP character
standard input file descriptor	suspend character
standard input stream 140	SVID 4
standard output file descriptor	symbolic link
standard output stream	syntax, for program arguments
standard streams	syntax, for reading numbers
standards 2	System V Unix
START character 340	
static allocation	m
STATUS character	${f T}$
status codes	TCP (Internet protocol)
status of a file	template, for printf
status of obstack	template, for scanf
sticky bit	TERM environment variable
STOP character	terminal flow control
stop signal	terminal identification
stopped job 496	terminal input queue
stopped jobs, continuing 514	terminal input queue, clearing 344
stopped jobs, detecting 509	terminal input signal
storage allocation	terminal line control functions 343
stream (sockets)	terminal line speed
stream, for I/O to a string	terminal mode data types 323
streams and descriptors	terminal mode functions
streams, and file descriptors	terminal output queue
streams, standard	terminal output queue, flushing 343
string	terminal output signal 413
string allocation	terminated jobs, detecting 509
string collation functions	termination signal
string comparison functions	testing access permission
string concatenation functions	testing exit status of child process
string copy functions	text stream
string length	ticks, clock
string literal	tilde expansion
string search functions	TIME termios slot
string stream	time zone
string, representation of	time, calendar
style of communication (of a socket)	time, elapsed CPU
subshell	timers, setting
substitution of variables and commands 125	timing error in signal handling 454
successive signals	TMPDIR environment variable
summer time	tokenizing strings
SunOS	transmitting datagrams
	trigonometric functions

type measurements, floating 576	variable substitution
type measurements, integer 574	variable-sized arrays 56
type modifier character (printf)	variadic function argument access 566
type modifier character (scanf)	variadic function prototypes 566
typeahead buffer	variadic functions
TZ environment variable	variadic functions, calling 568
	virtual time alarm signal
\mathbf{U}	virtual timer 387
umask	volatile declarations
unbuffered stream	
unconstrained storage allocation	***
undefining macros that shadow functions 6	\mathbf{W}
Unix, Berkeley	waiting for a signal
Unix, System V	waiting for completion of child process 488
unlinking a file	waiting for input or output
unreading characters	warnings of memory almost full 59
upper-case character	WERASE character
urgent data signal	whitespace character
urgent socket condition	wide characters 83
usage limits	width of integer type 574
user database	wildcard expansion 125
user ID	word expansion
user ID, determining 532	working directory
user name	write lock
user signals	writing to a file descriptor
usual file name syntax errors	writing to a socket
T 7	writing to a stream, by blocks
\mathbf{V}	writing to a stream, by characters
variable number of arguments 564	writing to a stream, formatted

		21.1.2	Concepts of Signal Generation	404
		21.1.3	How Signals Are Delivered	405
	21.2	Standard	Signals	406
		21.2.1	Program Error Signals	406
		21.2.2	Termination Signals	409
		21.2.3	Alarm Signals	411
		21.2.4	Asynchronous I/O Signals	411
		21.2.5	Job Control Signals	412
		21.2.6	Miscellaneous Signals	414
		21.2.7	Nonstandard Signals	414
		21.2.8	Signal Messages	415
	21.3	Specifyin	g Signal Actions	416
		21.3.1	Basic Signal Handling	416
		21.3.2	Advanced Signal Handling	419
		21.3.3	Interaction of signal and sigaction	421
		21.3.4	sigaction Function Example	421
		21.3.5	Flags for sigaction	423
		21.3.6	Initial Signal Actions	424
	21.4	Defining	Signal Handlers	
		21.4.1	Signal Handlers That Return	
		21.4.2	Handlers That Terminate the Process	

		21.4.3 Nonlocal Control Transfer in Handlers 42
		21.4.4 Signals Arriving While a Handler Runs 43
		21.4.5 Signals Close Together Merge into One
		21.4.6 Signal Handling and Nonreentrant Functions 43-
		21.4.7 Atomic Data Access and Signal Handling 43
		21.4.7.1 Example of Problems with Non-Atomic Access
		21.4.7.2 Atomic Types
		21.4.7.3 Atomic Usage Patterns
	21.5	Primitives Interrupted by Signals
	21.6	Generating Signals 440
		21.6.1 Signaling Yourself
		21.6.2 Signaling Another Process 44
		21.6.3 Permission for using kill
		21.6.4 Using kill for Communication
	21.7	Blocking Signals
		21.7.1 Why Blocking Signals is Useful
		21.7.2 Signal Sets
		21.7.3 Process Signal Mask
		21.7.4 Blocking to Test for Delivery of a Signal 44
		21.7.5 Blocking Signals for a Handler 456
		21.7.6 Checking for Pending Signals
		21.7.7 Remembering a Signal to Act On Later
	21.8	Waiting for a Signal
		21.8.1 Using pause
		21.8.2 Problems with pause
		21.8.3 Using sigsuspend
	21.9	BSD Signal Handling
		21.9.1 POSIX and BSD Signal Facilities
	21.10	BSD Function to Establish a Handler 45
		21.10.1 BSD Functions for Blocking Signals 460
		21.10.2 Using a Separate Signal Stack
20	Descri	and Stantum and Tannaination 166
22		ess Startup and Termination 463
	22.1	Program Arguments
		22.1.1 Program Argument Syntax Conventions 46
		22.1.2 Parsing Program Options
		22.1.3 Example of Parsing Arguments with getopt 460
		22.1.4 Parsing Long Options
		22.1.5 Example of Parsing Long Options
	22.2	Environment Variables
		22.2.1 Environment Access 473

		22.2.2 Standard Environment Variables
	22.3	Program Termination
		22.3.1 Normal Termination
		22.3.2 Exit Status
		22.3.3 Cleanups on Exit
		22.3.4 Aborting a Program
		22.3.5 Termination Internals
